Abstract

The combined analysis of νµ disappearance and νe appearance data of NOνA experiment leads to three nearly degenerate solutions. This degeneracy can be understood in terms of deviations in νe appearance signal, caused by unknown effects, with respect to the signal expected for a reference set of oscillations parameters. We define the reference set to be vacuum oscillations in the limit of maximal θ23 and no CP-violation. We then calculate the deviations induced in the νe appearance signal event rate by three unknown effects: (a) matter effects, due to normal or inverted hierarchy (b) octant effects, due to θ23 being in higher or lower octant and (c) CP-violation, whether δCP ∼ −π/2 or δCP ∼ π/2. We find that the deviation caused by each of these effects is the same for NOνA. The observed number of νe events in NOνA is equivalent to the increase caused by one of the effects. However, for the NOνA experiment, the νµ disappearance data prefers non-maximal θ23 and the matter effects are expected to change its νe appearance probability. Hence the νe appearance events in NOνA will definitely be modified by these two effects. Therefore, the observed number of νe appearance events of NOνA is the net result of the increase caused by two of the unknown effects and the decrease caused by the third. Thus we get the three degenerate solutions. We also find that further data by NOνA can not distinguish between these degenerate solutions but addition of one year of neutrino run of DUNE can make a distinction between all three solutions. The distinction between the two NH solutions and the IH solution becomes possible because of the larger matter effect in DUNE. The distinction between the two NH solutions with different octants is a result of the synergy between the anti-neutrino data of NOνA and the neutrino data of DUNE.

I. INTRODUCTION

The data from the solar [1, 2] and the atmospheric [3, 4] neutrino experiments led to the discovery of neutrino oscillations. Both the solar and the atmospheric neutrino anomalies can be explained in terms of the oscillations of the three neutrino flavours, $\nu_e$, $\nu_\mu$ and $\nu_\tau$, into one another. The oscillation probabilities depend on two independent mass-squared differences, $\Delta_{21}$ and $\Delta_{31}$, three mixing angles, $\theta_{12}$, $\theta_{13}$ and $\theta_{23}$, and a CP-violating phase $\delta_{CP}$. Among these parameters, there are two small quantities: the angle $\theta_{13}$ and the ratio $\Delta_{21}/\Delta_{31}$.

During the past decade and a half, a number of experiments with man-made neutrino sources have made precision measurements of the mass-squared differences and the mixing angles. This was possible because the expressions for the three flavour survival probabilities reduce to those of effective two flavour survival probabilities, under appropriate approximations. For example, setting $\theta_{13} = 0$ in $P(\bar{\nu}_e \rightarrow \bar{\nu}_e)$ expression for KamLAND [5, 6] experiment reduces it to an effective two flavour survival probability in terms of $\Delta_{21}$ and $\theta_{12}$. A similar effective two flavour survival probability, in terms of $\Delta_{31}$ and $\theta_{23}$, for MINOS [7] experiment can be obtained by setting $\theta_{13} = 0 = \Delta_{21}$ in the expression for $P(\nu_\mu \rightarrow \nu_\mu)$. For the short baseline reactor neutrino experiments, Double-CHOOZ [8], Daya-Bay [9] and RENO [10], an effective two flavour expression in terms of $\Delta_{31}$ and $\theta_{13}$ is obtained by setting $\Delta_{21} = 0$ in the expression for $P(\bar{\nu}_e \rightarrow \bar{\nu}_e)$. This reduction to effective two flavour expressions leads to accurate measurement of the modulus of the mass-squared differences and $\sin^2 2\theta_{ij}$. The solar neutrino data requires $\Delta_{21}$ to be positive but the sign of $\Delta_{31}$ is still unknown. The value of $\sin^2 2\theta_{23}$ is measured quite accurately but, since it is close to 1, there is a large uncertainty in the value of $\sin^2 \theta_{23}$. There is no measurement yet of the CP-violating phase $\delta_{CP}$. The best-fit values and the allowed 1 $\sigma$ and 3 $\sigma$ of the mass-squared differences and the mixing angles from the disappearance data of the above experiments plus the solar and the atmospheric data is given in table I.

At present the two long baseline accelerator experiments, T2K and NO$\nu$A, are taking data [12–15]. These experiments observe $\nu_\mu \rightarrow \nu_e$ appearance as well as $\nu_\mu$ disappearance. The dominant oscillations for these experiments are driven by $\Delta_{31}$. These experiments are also designed to be sensitive to CP-violation in neutrino oscillations. Hence they are also sensitive to $\Delta_{21}$ dependent sub-dominant term in the oscillation probability. Thus the data

| \(\Delta m^2/10^{-3}\) eV\(^2\) (NH)       | 2.524    | 2.484 - 2.563       | 2.407 - 2.643     |
| \(\Delta m^2/10^{-3}\) eV\(^2\) (IH)       | -2.514   | -2.555 - -2.476     | -2.635 - -2.399   |
| \(\sin^2 \theta_{13}\) (NH)                | 0.02166  | 0.02091 - 0.02241   | 0.01934 - 0.02392 |
| \(\sin^2 \theta_{13}\) (IH)                | 0.02179  | 0.02103 - 0.02255   | 0.01953 - 0.02408 |
| \(\sin^2 \theta_{23}\) (NH)                | 0.441    | 0.420 - 0.468       | 0.385 - 0.635     |
| \(\sin^2 \theta_{23}\) (IH)                | 0.587    | 0.563 - 0.607       | 0.393 - 0.640     |

of these two experiments must necessarily be analysed using the full three flavour expressions for the neutrino survival (\(\nu_\mu\) disappearance) and oscillation (\(\nu_e\) appearance) probabilities. Since these probabilities depend on a number of parameters, degenerate solutions arise when they are fit to the data. In particular, the \(\nu_\mu \rightarrow \nu_e\) appearance probability depends on three unknowns: (a) neutrino mass hierarchy (\(\Delta_{31} > 0\) or \(\Delta_{31} < 0\)), (b) \(\theta_{23}\) octant (\(\theta_{23} > \pi/4\) or \(\theta_{23} < \pi/4\)) and (c) value of \(\delta_{\mathrm{CP}}\). In this report, we study how the three degenerate solutions of NO\(\nu\)A arise due to the above three unknowns. We also investigate how the DUNE [16] experiment can fully resolve this three fold degeneracy.

II. DEGENERACIES IN \(P(\nu_\mu \rightarrow \nu_e)\)

In T2K and NO\(\nu\)A experiments, the neutrinos travel long distances through earth matter and undergo coherent forward scattering. The effect of this scattering is taken into account through the Wolfenstein matter term [17]

\[
A \ (\text{in eV}^2) = 0.76 \times 10^{-4} \rho \ (\text{in gm/cc}) \ E \ (\text{in GeV}),
\]

where \(E\) is the energy of the neutrino and \(\rho\) is the density of the matter. The interference between \(A\) and \(\Delta_{31}\) leads to the modification of neutrino oscillation probability due to matter
effects. This modified expression for $P(\nu_\mu \to \nu_e)$ is given by [18, 19]

$$P(\nu_\mu \to \nu_e) = P_{\mu e} = \sin^2 2\theta_{13} \sin^2 \theta_{23} \frac{\sin^2 \hat{\Delta}(1 - \hat{A})}{(1 - \hat{A})^2}$$

$$+ \alpha \cos \theta_{13} \sin 2\theta_{12} \sin 2\theta_{13} \sin 2\theta_{23} \cos(\hat{\Delta} + \delta_{\text{CP}}) \frac{\sin \hat{\Delta} \hat{A} \sin (1 - \hat{A})}{\hat{A}}$$

$$+ \alpha^2 \sin^2 2\theta_{12} \cos^2 \theta_{13} \cos^2 \theta_{23} \frac{\sin^2 \hat{\Delta} \hat{A}}{\hat{A}^2},$$

(2)

where $\hat{\Delta} = 1.27\Delta_{31} L/E$, $\hat{A} = A/\Delta_{31}$ and $\alpha = \Delta_{21}/\Delta_{31}$. For anti-neutrinos, $P(\bar{\nu}_\mu \to \bar{\nu}_e) = P_{\bar{\mu}e}$ is given by a similar expression with $\delta_{\text{CP}} \to -\delta_{\text{CP}}$ and $A \to -A$. Since $\alpha \approx 0.03$, the term proportional to $\alpha^2$ in $P_{\mu e}$ can be neglected. Since the experiments are designed to be sensitive to $\delta_{\text{CP}}$, the second term, proportional to $\alpha$ must be retained. If $\delta_{\text{CP}}$ is in the lower half plane (LHP, $-180^\circ \leq \delta_{\text{CP}} \leq 0$) $P_{\mu e}$ is larger compared to the CP conserving case whereas it is smaller for $\delta_{\text{CP}}$ in the upper half plane (UHP, $0 \leq \delta_{\text{CP}} \leq 180^\circ$). For $P_{\bar{\mu}e}$ the situation is reversed. For the purpose of discussion in the paragraph below, we take $\delta_{\text{CP}}$ to be a binary variable which either increases $P_{\mu e}$ or decreases it.

The dominant term in $P_{\mu e}$ is proportional to $\sin^2 2\theta_{13}$ and hence this probability is rather small. Matter effect can enhance (suppress) it by about 22% for NO$\nu$A if $\Delta_{31}$ is positive (negative) [20]. The situation is opposite for $P_{\bar{\mu}e}$. Since each unknown can take two possible values, there are eight different combinations of the three unknowns. A given value of $P_{\mu e}$ can be reproduced, for any combination of the unknowns, by choosing the value of $\theta_{13}$ appropriately. Thus there is an eight-fold degeneracy in interpreting the expression for $P_{\mu e}$, if the value of $\sin^2 2\theta_{13}$ is not known precisely. We will show below that the present precision measurement of $\theta_{13}$ breaks this eight-fold degeneracy into $(1 + 3 + 3 + 1)$ pattern.

III. $\nu_e$ APPEARANCE EVENTS IN NO$\nu$A

A. 2017 analysis

NO$\nu$A [15] is a long baseline neutrino oscillation experiment capable of measuring the survival probability $P(\nu_\mu \to \nu_\mu)$ and the oscillation probability $P(\nu_\mu \to \nu_e)$. The NuMI beam at Fermilab, with a power of 700 kW which corresponds to $6 \times 10^{20}$ protons on target (POT) per year, produces the neutrinos. The far detector consists of 14 kton of totally active scintillator material and is located 810 km away at a 0.8° off-axis location. Due to the
off-axis location, the flux peaks sharply at 2 GeV, which is close to the energy of maximum
oscillation of 1.4 GeV. It has started taking data in 2014 and is expected to run three
years in neutrino mode and three years in anti-neutrino mode. The combined analysis of $\nu_\mu$
disappearance and $\nu_e$ appearance data is given in ref. [21], which is based on a neutrino run
with $6.05 \times 10^{20}$ POT. This analysis gives the following three (almost) degenerate solutions
for the unknown quantities:

1. normal hierarchy ($\Delta_{31} +ve$), $\sin^2 \theta_{23} = 0.4$, $\delta_{CP} = -90^\circ$ (NH, LO, $-90^\circ$),

2. normal hierarchy ($\Delta_{31} +ve$), $\sin^2 \theta_{23} = 0.62$, $\delta_{CP} = 135^\circ$ (NH, HO, $135^\circ$) and

3. inverted hierarchy ($\Delta_{31} -ve$), $\sin^2 \theta_{23} = 0.62$, $\delta_{CP} = -90^\circ$ (IH, HO, $-90^\circ$).

To understand the existence of the above three solutions, we first calculate $\nu_e$ appearance
in NO$\nu$A for the case of vacuum oscillations with $\theta_{23} = 45^\circ$ and $\delta_{CP} = 0$. We then consider
the changes in this number due to (a) matter effects, (b) $\theta_{23}$ octant effect and (c) large value
of $\delta_{CP}$. First we introduce one change at a time in the following manner:

- normal hierarchy (NH), which increases $P_{\mu e}$ or inverted hierarchy (IH) which decreases
  it,

- higher octant (HO), which increases $P_{\mu e}$ or lower octant (LO) which decreases it and

- $\delta_{CP} = -90^\circ$, which increases $P_{\mu e}$ or $\delta_{CP} = +90^\circ$, which decreases it.

The event numbers are calculated using GLoBES software [22, 23]. The following inputs
are used for the well-measured neutrino parameters: $\Delta_{21} = 7.5 \times 10^{-5}$ eV$^2$, $\sin^2 \theta_{12} = 0.306$,
$\Delta_{31} (\text{NH}) = 2.74 \times 10^{-3}$ eV$^2$, $\Delta_{31} (\text{IH}) = -2.65 \times 10^{-3}$ eV$^2$ and $\sin^2 2\theta_{13} = 0.085$. The values
of $\Delta_{31} (\text{NH})$ and $\Delta_{31} (\text{IH})$ are taken from the fit to NO$\nu$A disappearance data [24]. The
inputs for the undetermined parameters are taken to be one of three possible values: the
reference value mentioned at the beginning of the paragraph (labelled ‘0’), the value which
increases $P_{\mu e}$ (labelled ‘+’) and the one which decreases it (labelled ‘−’). The results are
displayed in table II. From this table, we note that the increase in $\nu_e$ appearance events, for
any single ‘+’ change of the undetermined parameters, is essentially the same. A similar
comment applies to the case of any single ‘−’ change.

Next we consider all the eight possible combinations in the changes of the three undeter-
dined parameters. For example, all three may shift in such a way that each shift leads to
increase in $P_{\mu e}$. We label this case as $(+++)$.

In such a case, we get the maximum number of $\nu_e$ appearance events. Another case is that two of the undetermined parameters shift so as to increase $P_{\mu e}$ whereas the third parameter shifts to lower it. This can occur in three possible ways, which we label as $(+ + -)$, $(+ - +)$ and $(++ +)$. These three combinations predict a moderate increase in the number of $\nu_e$ appearance events compared to the reference case. Similarly there is a case where shift in one parameter increases $P_{\mu e}$ but shifts in the other two lower it, with the three possibilities $(+ - -)$, $(-- +)$ and $(--+)$, which predict a moderate decrease in the number of $\nu_e$ appearance events compared to the reference case. Finally, there is a case where each of the three shifts lowers $P_{\mu e}$, labelled $(-- -)$, which predicts the smallest number of $\nu_e$ appearance events. The number of $\nu_e$ appearance events for NO\nuA, for each of the above eight combinations, are listed in table III, which are also calculated using GLoBES. From this table, we note that the number of events for the three combinations $(++ -)$, $(+ - +)$ and $(++ +)$ are nearly the same. Such a statement is also true for $(+- -)$, $(-- +)$ and $(--+)$ combinations. The predictions for the combinations $(++ +)$ and $(-- -)$ are unique. Thus the eight-fold degeneracy, which was present when $\theta_{13}$ was not measured, splits into $(1 + 3 + 3 + 1)$ pattern with the precision measurement of $\theta_{13}$ [25], as mentioned in the introduction. The $\nu_e$ appearance data of NO\nuA shows a modest increase relative to the reference case. Hence there is a three-fold degeneracy in NO\nuA solutions. The predictions of $\nu_e$ appearance events, for each of the three NO\nuA solutions,

**TABLE IV:** Number of expected ν_e appearance events for one year ν run of NOνA, for the three solutions in ref. [21].

are listed in table IV. The predictions for the two NH solutions matched the experimental numbers. The prediction for the IH solution, which is 0.5σ away from the NH solutions, is lower by 3 (half the statistical uncertainty in the expected number). A more detailed calculation shows that the agreement is valid for ν_e appearance spectrum also. We have verified this through GLoBES simulations.

We now consider if it is possible to resolve this three-fold degeneracy with anti-neutrino data from NOνA. For anti-neutrinos the sign of matter term \( A \) is reversed and so is the sign of \( δ_{CP} \). The probability \( P_{\bar{\mu}e} \) decreases (increases) for NH (IH). It also increases (decreases) for \( δ_{CP} \) in UHP (LHP). However, we will continue to label NH by ‘+’ and IH by ‘−’. Similarly we

will label LHP by ‘+’ and UHP by ‘-’. But, it should be remembered that, for anti-neutrinos, ‘+’ sign (‘-’ sign) for hierarchy and $\delta_{CP}$ leads to a decrease (increase) in event rates. For octant, however, ‘+’ sign (‘-’ sign) lead to increase (decrease) in $P_{\bar{\mu}\bar{\nu}_e}$ also. For the ($+$ $-$) solution of NO$\nu$A the value of $P_{\bar{\mu}\bar{\nu}_e}$ decreases due to hierarchy and increases due to octant and $\delta_{CP}$. For the ($-$ $+$) solution, $P_{\bar{\mu}\bar{\nu}_e}$ increases due to hierarchy and octant and decreases due to $\delta_{CP}$. Hence, these two solutions are degenerate for anti-neutrino data also and NO$\nu$A data can not distinguished between them. In the case of the third ($+$ $-$) solution, $P_{\bar{\mu}\bar{\nu}_e}$ decreases due to all three unknowns. The prediction for $\bar{\nu}_e$ appearance events for this solution will be the smallest. In principle, the anti-neutrino data of NO$\nu$A should distinguish the ($+$ $-$) solution from the other two. Since the expected number of $\bar{\nu}_e$ appearance events for this case are particularly small, as we can see from table V, the statistical uncertainties are very large. So it is difficult for NO$\nu$A to distinguish this solution from the other two at 3 $\sigma$ level.

We illustrate our results in fig. 1. The plots in this figure are prepared using the following procedure. Each of the three solutions was used as the input point in GLoBES to obtain disappearance and appearance event spectra of NO$\nu$A for a three year neutrino run and a three year anti-neutrino run, which we label as ($3\nu + 3\bar{\nu}$) run. The input values of the fixed neutrino parameters are given previously. These spectra are contrasted with the simulated spectra, also calculated using GLoBES, where the test values of undetermined parameters are varied over the following ranges: test hierarchy – NH or IH, test $\sin^2\theta_{23}$ – (0.3, 0.7) and test $\delta_{CP}$ – ($-180^\circ, +180^\circ$). The $\chi^2$ between the spectra with NO$\nu$A best-fit point as input and the simulated spectra with test values as input is computed. The plots in the top row show the allowed regions in $\delta_{CP}$ – $\sin^2\theta_{23}$ plane at 3 $\sigma$ C.L., by this ($3\nu + 3\bar{\nu}$) run. We see that for a given solution of NO$\nu$A the other two solutions are not ruled out at 3 $\sigma$ level [26].
FIG. 1: Expected allowed regions in $\sin^2 \theta_{23} - \delta_{CP}$ plane for a six years run of NO$\nu$A, assuming one of the best-fit points is the true solution. The left, middle and right columns represent (NH, LO, $-90^\circ$), (NH, HO, $135^\circ$) and (IH, HO, $-90^\circ$) solutions respectively. The top and bottom rows are for (3$\nu$ + 3$\bar{\nu}$) and (1$\nu$ + 5$\bar{\nu}$) runs of NO$\nu$A respectively. The blue (red) curves are there for test NH (IH).

These plots show that the two solutions, (NH, HO, $135^\circ$) and (IH, HO, $-90^\circ$) cannot be distinguished from each other, as explained above. Due to the anti-neutrino data, the (NH, LO, $-90^\circ$) solution is partly isolated. But the large statistical errors in the anti-neutrino data do not allow a complete isolation. We have also done the simulation for a one year neutrino run followed by a five year anti-neutrino run of NO$\nu$A, which we label as (1$\nu$ + 5$\bar{\nu}$) run. It was hoped that the increased anti-neutrino statistics may help in isolating the (NH, LO, $-90^\circ$) solution. Despite the increased exposure, the number of $\bar{\nu}_e$ appearance events is too small to distinguish the (NH, LO, $-90^\circ$) solution. This can be seen from the three plots in the bottom row of fig. 1. We have also checked the discrimination capabilities of (4$\nu$ + 2$\bar{\nu}$) and (2$\nu$ + 4$\bar{\nu}$) runs. They are not noticeably different from those of the (3$\nu$ + 3$\bar{\nu}$) run.
TABLE VI: Number of expected $\nu_e$ appearance events for one year $\nu$ run of DUNE, for the three solutions in ref. [21].

| Hierarchy–$\sin^2 \theta_{23}$–$\delta_{\text{CP}}$ | Signal eve. | Bg eve. | Total eve. |
|--------------------------------------------------|-------------|---------|------------|
| NH–0.404– -86                                    | 332.22      | 97.91   | 430.13     |
| NH–0.62– +135                                    | 353.12      | 97.81   | 450.93     |
| IH–0.62– -90                                     | 220.09      | 100.03  | 320.12     |

From fig. 2, we see that the addition of one year of neutrino data of DUNE to NO$\nu$A data of $(3\nu + 3\bar{\nu})$ run leads to an essentially unique identification of the correct solution at 3$\sigma$ level. The average neutrino energy for the DUNE experiment is larger than the energy of NO$\nu$A and hence its matter effect is larger. Therefore, the change in $\nu_e$ appearance events induced by matter effects is larger compared to the changes induced by octant effects or by $\delta_{\text{CP}}$. This sets apart the IH solution from the two NH solutions. There is a modest difference in the prediction of $\nu_e$ appearance events for the two NH solutions with different octants of $\theta_{23}$, as shown in table VI. This difference, combined with the discriminating power of NO$\nu$A anti-neutrino data, leads to a 3 $\sigma$ distinction between the two NH solutions. Thus the synergy between the anti-neutrino data of NO$\nu$A and the neutrino data of DUNE plays an important role in distinguishing between the two NH solutions. In ref. [26] the combination of NO$\nu$A $(3\nu + 3\bar{\nu})$ run along with DUNE $(1\nu + 1\bar{\nu})$ run was considered. Their results are very similar to our results. We have not included T2K in these simulations because its best-fit value of $\sin^2 \theta_{23}$ [14] does not agree with any of the solutions given in ref. [21].

B. 2018 data

During the past year, the NO$\nu$A collaboration has re-calibrated their signal identification algorithms [27]. In addition they have accumulated more data. As a result of the analysis with the new procedure, NO$\nu$A finds a best-fit solution in the higher octant at (NH, $\sin^2 \theta_{23} = 0.56$, $\delta_{\text{CP}} = -144^\circ$). There is a nearly degenerate solution in the lower octant at (NH, $\sin^2 \theta_{23} = 0.47$, $\delta_{\text{CP}} = -72^\circ$). There is no IH solution at 1 $\sigma$. In this subsection, we discuss
FIG. 2: Expected allowed regions in $\sin^2 \theta_{23} - \delta_{CP}$ plane for a $(3\nu + 3\bar{\nu})$ run of NO$\nu$A plus a one year neutrino run of DUNE, assuming one of the three solutions in ref. [21] is the true solution. The left, middle and right panels represent (NH, LO, $-90^\circ$), (NH, HO, $135^\circ$) and (IH, HO, $-90^\circ$) solutions respectively. The blue (red) curves are there for test NH (IH).

the ability of long baseline neutrino experiments to distinguish between these two solutions.

We study this discrimination ability using the same procedure as before. The parameters of the HO solution are used as input to GLoBES and the neutrino and anti-neutrino event spectra are simulated. We also use GLoBES to simulate these spectra for various ‘test’ values of the neutrino oscillation parameters and compute the $\chi^2$ between the spectrum of the HO solution and each of the test spectra. This computation is done for for three different situations: for NO$\nu$A simulations alone, for NO$\nu$A + T2K simulations and for NO$\nu$A + T2K + DUNE simulations. The same procedure is repeated for the LO solution. In dealing with these new solutions, we have included the simulation of T2K data also, because the newly allowed values of $\sin^2 \theta_{23}$ agree with T2K best-fit value [14].

The results are shown in fig. 3 and fig. 4. In each figure, NH (IH) is the test hierarchy for the top (bottom) row. The plots in the left column are for NO$\nu$A $(3\nu + 3\bar{\nu})$ run, those in the middle column are for the combination of NO$\nu$A $(3\nu + 3\bar{\nu})$ run and T2K $(3\nu + 3\bar{\nu})$ run and those in the right column are for the above combination along with a one year neutrino run of DUNE. We see from the bottom rows of these two figures that neither NO$\nu$A alone nor NO$\nu$A + T2K can rule out the IH (the wrong hierarchy) at $3 \sigma$ level. However, the addition of one year of neutrino data from DUNE is very effective in ruling out the wrong hierarchy.
Turning our attention to the discrimination between the two different octant solutions, we find that the data from NOνA alone can not distinguish between them. Addition of T2K data helps in reducing the allowed regions a little but still does not provide a discrimination between the two octants. T2K data strongly discriminates against δ_{CP} ≈ 90° hence the test values around this region are ruled out at 3 σ, though they are allowed by NOνA data. One year neutrino data of DUNE, which has a modest octant discrimination power, is able to rule out the wrong octant at 1 σ but not at 3 σ. Neither NOνA nor NOνA + T2K can establish CP violation at 3 σ.

We have also done a simulation of DUNE (5ν + 5ν̄) run to check how well CP violation can be established. The results are shown in fig. 5. The left panel is for the LO solution and the right panel is for the HO solution. These figures are the result of NOνA (3ν + 3ν̄), T2K (3ν + 3ν̄) and DUNE (5ν + 5ν̄) runs. The plots in these figures denote 1 σ, 3 σ and 5 σ.
FIG. 4: Allowed regions in $\sin^2 \theta_{23} - \delta_{\text{CP}}$ parameter space assuming the LO solution is correct. The left, middle and right columns are for NOνA (3ν + 3¯ν), NOνA (3ν + 3¯ν) + T2K (3ν + 3¯ν) and NOνA (3ν + 3¯ν) + T2K (3ν + 3¯ν) + DUNE (1ν) respectively. The top (bottom) row is for test NH (IH).

allowed contours. We note that, for LO solution, CP-violation can be established at 5 $\sigma$. But, for the HO solution, $\delta_{\text{CP}} = 180^\circ$ is not ruled out at 5 $\sigma$. The addition of (5ν + 5¯ν) run of DUNE also helps in distinguishing between the two solutions at 3 $\sigma$ level.

This result can be understood from the point of view of changes in $\nu_e$ appearance events induced by matter effects, octant effects and $\delta_{\text{CP}}$ effects on the reference point of vacuum oscillations, maximal mixing and no CP-violation. NOνA experiment observes certain number of $\nu_e$ appearance events. This number is moderately larger than the number of such events expected from the reference point. The question is: which of the three effects is contributing to this excess? The analysis of the data prefers NH as the hierarchy but has no preference for either octant. Since the excess number of $\nu_e$ events is fixed, we can consider two possibilities:
Part of the excess is because $\theta_{23}$ is in the higher octant. That means only a limited part of the excess is due to $\delta_{CP}$ effect. Values of $\delta_{CP}$ in the lower half plane lead to an increase in $\nu_e$ appearance, with the maximum increase coming for the case of $\delta_{CP} = -90^\circ$. If the $\delta_{CP}$ effects are to lead to only a modest excess, then the preferred value of $\delta_{CP}$ will be away from $-90^\circ$. In the present case it is $-144^\circ$, closer to the CP conserving value of $-180^\circ$ than the maximal CP-violating value of $-90^\circ$.

If $\theta_{23}$ is in the lower octant, then the octant effects suppress $\nu_e$ events. To obtain the observed excess, then the $\delta_{CP}$ effects have to compensate this suppression and provide the excess. In such a situation, the preferred value of $\delta_{CP}$ will be in the neighbourhood of maximal CP-violation. In the present case, it is $-72^\circ$, closer to maximal CP-violation rather than the CP conserving value of $0/180^\circ$.

It is, of course, easier to establish CP-violation if the value of $\delta_{CP}$ is close to $-90^\circ$.

### IV. CONCLUSIONS

In this report, we have discussed the degeneracies present in the NOνA data. Before the measurement of $\theta_{13}$, $P_{\mu e}$ had an eight fold degeneracy, arising due to the three unknown binomial variables: hierarchy, octant of $\theta_{23}$ and half plane of $\delta_{CP}$. However, the precision measurement of $\theta_{13}$ has split this degeneracy into the pattern $(1+3+3+1)$. If the observed
number of $\nu_e$ events are well above or well below those expected from the reference point of vacuum oscillations with maximal $\theta_{23}$ and no CP-violation, then one can uniquely determine the hierarchy, octant and $\delta_{CP}$. If the difference between observed events and those expected from reference point is moderate, then, in general, there will be three degenerate solutions: One solution whose octant is distinct from that of the other two, a second solution whose half plane of $\delta_{CP}$ is distinct from that of other two and a third solution whose hierarchy is distinct from that of the other two. The early neutrino data of NO$\nu$A [21], which showed a modest excess of $\nu_e$ appearance events, gave rise to the three solutions, (NH, LO, $-90^\circ$), (NH, HO, 135$^\circ$) and (IH, HO, $-90^\circ$). These solutions do indeed have the pattern described above.

In this report, we have shown that NO$\nu$A will not be able to make a distinction between any of these three solutions. The two higher octant solutions are completely degenerate with respect to both neutrino and anti-neutrino data of NO$\nu$A. The lower octant solution is distinct from the point of view of anti-neutrino data but the expected $\bar{\nu}_e$ events are quite small. The corresponding large statistical errors prevent a clean isolation of this solution. However, the addition of one year of neutrino data from DUNE can effectively isolate each of these three solutions at $3\sigma$. The two NH solutions can be discriminated from the IH
solution because of the large matter effects in DUNE. Between the two NH solutions of different octants, both the anti-neutrino data of NOνA and the neutrino data of DUNE have a moderate discriminating capability. The synergy between these two sets of data is capable of providing a 3σ discrimination between these two NH solutions.

Later data of NOνA, based on a more refined signal identification algorithm [27], has only two degenerate solutions: both with NH but with different octants, where sin²θ₂₃ values in both cases are closer to maximal mixing. This is a consequence of the new procedure, which has identified a larger number of signal events leading to a fairly large excess of νₑ events compared to the expectation from the reference point. A significant part of this excess occurs due to the matter effects of NH. There are two possibilities to explain the remainder of the excess:

- part of it is due to higher octant value of θ₂₃ and part of it is due to the δ_CP in lower half plane but well away from the maximal CP-violation of −90°

- a small suppression due to lower octant value of θ₂₃ and a moderately large increase due to δ_CP being in the neighbourhood of the maximal CP-violation value −90°.

We found that neither NOνA nor NOνA + T2K is capable of distinguishing between these two solutions at 3σ level nor can they rule out the wrong hierarchy. But addition of one year of neutrino data of DUNE is capable of ruling out the wrong hierarchy at 3σ level but is unable to provide a similar discrimination between the two solutions. Addition of a (5ν + 5ν̄) run of the DUNE experiment can distinguish between the solutions at 3σ. It can also establish CP-violation at 5σ level for the lower octant solution but not for the higher octant solution. This occurs because the δ_CP value of the lower octant solution is closer to maximal CP-violation.
