Research
Abstract

Background

In low- and middle-income countries, the prevalence of antimicrobial resistance (AMR) is increasing. To control AMR, WHO recommends monitoring antibiotic use, in particular Watch antibiotics. These are critically important antibiotics, with restricted use because at risk of becoming ineffective due to increasing AMR. We investigated pre-hospital antibiotic use in rural Burkina Faso.

Methods

During 2016-2017, we collected data from patients aged >3 months presenting with severe acute fever to the rural hospital of Nanoro Health District, Burkina Faso, including antibiotic use in the two weeks prior to consultation or hospitalization. We analysed reported antibiotic use with the WHO Access, Watch, Reserve (AWaRe) classification.

Results

Of 920 febrile participants (63.0% ≤ 14 years), pre-hospital antibiotic use was reported by 363 (39.5%). Among these 363, microbiological diagnoses were confirmed for 275 (75.8%) patients, of which 162 (58.9%) were non-bacterial infections. Use of more than one antibiotic was reported by 58/363 (16.0%) participants. Of 491 patients who did not previously visit a primary health center, 131 (26.7%) reported antibiotic use. Of 424 antibiotics reported, 263 (62.0%) were Access and 159 (37.5%) Watch antibiotics. Watch antibiotic use was more frequent among patients >14 year olds (51.1%) compared to those 0-14 year old (30.7%) and among referrals from the primary health centers (42.2%) compared to self-referred patients (28.1%). Most frequently reported Watch antibiotics were ceftriaxone (114, 71.7%) and ciprofloxacin (32, 20.1%).

Conclusion

The reported frequent use of Watch group antibiotics among febrile patients prior to presentation to the hospital in rural Burkina Faso highlights the need to develop targeted interventions to improve antibiotic use in community settings as part of strengthening antibiotic stewardship in low- and middle-income countries. This should include facilitating referral, access to qualified prescribers and diagnostic tools in rural primary health centers.

Trial registration

: ClinicalTrials.gov identifier: NCT02669823. Registration date was February 1, 2016

Introduction
The emergence of antimicrobial resistance (AMR) is driven by appropriate and inappropriate use of antimicrobials. Increasing microorganisms’ exposure to antibiotics results in selection pressure, while suboptimal dosage allows selective survival of resistant microorganisms (1). Globally, mortality attributable to AMR infections has been estimated to increase from 700,000 annual deaths in 2014 to 10 million in 2050 (2). The World Health Organization's 2015 Global Action Plan on AMR urges a.o. to strengthen surveillance of AMR and antibiotic use, and to optimize the use of antibiotics (3). A global surveillance network for monitoring concurrently AMR and antibiotic use, the Global Antimicrobial Resistance Surveillance System (GLASS), has since been set up, reporting country-wide AMR prevalence of key human pathogens and antibiotics (4). To monitor antibiotic use, WHO proposed a classification of antibiotics for human use in three groups, "Access", "Watch" and "Reserve", according to their clinical importance, specific recommendations for their appropriate use, and resistance potential (5). Antibiotic sales data during 2000-2015 showed that the human use of so-called Watch antibiotics, critically important antibiotics particularly at risk of AMR emergence, was declining in high-income countries, while importantly increasing in middle income countries for which data were available (6,7).

In sub-Saharan Africa, self-medication with over-the-counter antibiotics from private pharmacies or informal drug stores, without prior prescription by a qualified health worker, is frequent and facilitates inappropriate antibiotic use (7–10). To optimize antibiotic use, it is crucial to understand the epidemiology of antibiotic use, in the community as well as in the hospital. Furthermore, also in local primary health centers, antibiotic prescriptions are not always rational (8,11). Peripheral health workers’ poor understanding of the correct use of antibiotics and risks of AMR, limited availability and use of diagnostic tools and difficult access to qualified referral healthcare are likely to be fuelling irrational prescribing of antibiotics (12,13). National level antibiotic consumption estimated from wholesale data, as in Burkina Faso, is limited to the official healthcare sector and usually aggregates in- and outpatient use (14). To our knowledge, no studies so far have investigated community-level antibiotic use. The purpose of this study is to understand community-level antibiotic use in febrile patients prior to presentation to the hospital in a rural district of Burkina Faso.

**Methods**

**Study population**

From March 23, 2016 to June 30, 2017, the PaluBac study recruited patients aged >3 months presenting to the Nanoro district hospital with acute fever (tympanic temperature \( \geq 38.0 ^\circ C \)) or history of fever in the last 48 hours and \( \geq 1 \) symptom(s) of respiratory distress, generalized weakness (prostration), impaired consciousness, seizures (one or more episodes), clinical jaundice, signs of shock, or with suspected severe malaria, invasive bacterial infection, or severe viral infection. From March 23 to November 8, 2016, only inpatients were recruited; from November 9, 2016 to June 30, 2017 also outpatients were included. PaluBac evaluated the performance of an automated cell counter to quantify malaria parasitaemia (15). Our embedded cross-sectional study recorded patients’ antibiotic use before presenting to the district hospital.

The study was conducted in the Nanoro Health District in the West-Central region of Burkina Faso, about 90 km from Ouagadougou, the capital city of Burkina Faso. The district has 24 primary health centers and one district hospital, “Centre Médical avec Antenne Chirurgicale” (CMA). Primary health centers are meant to be the...
patients’ first point of contact with the healthcare system, during outpatient consultations. There are no medical doctors attached. More complicated cases are referred from the primary health centers to the district hospital (16). The district hospital has hospitalization units, medical doctors and a clinical microbiology laboratory. In the health district, the most frequently reported diagnosis is malaria (17), in children often associated with a community-acquired invasive bacterial co-infection (18,19). Malaria is endemic with a high malaria transmission season from July to November. This period overlaps with the rainy season, which extends from June to October. The low malaria transmission season is from December to June.

**Antibiotics dispensing in Burkina Faso**

In Burkina Faso health districts, antibiotics can be obtained from formal public or private drug stores after prescription by a Medical Doctor or a nurse. Importation and quality of antibiotics (and medicines in general) is under the control of the national pharmaceutical regulatory agency (20). However, some drugs escape from this control and are available over-the-counter in public places such as markets (21). Also in formal drug stores, antibiotics can be purchased without prior consultation or prescription. In primary health centers, the only diagnostic tools available to support febrile diseases management are malaria rapid diagnostic tests (RDT). If such tests show a negative result, this usually leads to systematic antibiotic prescription (22).

**Data collection**

At inclusion, study clinicians completed case report forms with medical history, including the use of antibiotics and antimalarials in the two weeks prior to consultation at the district hospital, which we refer to as pre-hospital antibiotic use, the date of symptom onset, and whether the patient was referred or not from a primary health center. Referral patients first attended a primary health center where a nurse decided about the need for higher-level care and referral to the district hospital, based on clinical symptoms. Proper inpatient care is not possible at a primary health center, the patient can only be observed for a maximum of 48 hours. Self-referred patients were those presenting directly at the district hospital without first attending a primary health center.

**Data analysis**

Pre-hospital antibiotics were classified (i) according to WHO's Access, Watch, Reserve (AWaRe) classification and (ii) according to products name as stated in the WHO essential medicines list (5). For the latter, we combined ampicillin and amoxicillin use into one category (“ampicillin or amoxicillin”), and zoomed in on the use of the most prevalently prescribed antibiotic in the Watch group in particular. Anti-tuberculosis drugs were excluded from analysis. We report frequencies of antibiotics used by product name and by AWaRe group, of the use of more than one antibiotic, and compared by age (0-14 years vs >14 years), by malaria transmission season, by hospitalisation status after arrival to the hospital (in- vs outpatients) and by referral vs self-referred, using chi-square tests. We stratified the frequencies of pre-admission antibiotic use by malaria transmission season. Data was analysed with Stata 14.

**Results**

**Characteristics of the study population**

Of 1212 screened febrile patients, 930 patients were included in the study of whom 920 (75.9%) had data on antibiotic use recorded. Only the latter were considered in these analyses. 580 (63.0%) were children aged 0-14
years and 533 (57.9%) were male. A total of 428 (46.5%) patients were referrals from primary health centers; 344 (37.4%) patients were hospitalized upon arrival at the district hospital.

Table 1: characteristics of the study population

Pre-hospital antibiotic use

Pre-hospital antibiotic use was reported by 363/920 (39.5%) patients, of whom 58 (16.0%) used more than one antibiotic. This use was more prevalent among 0-14 year olds (240, 41.4%) than among those >14 (123, 36.2%) (p=0.12). Referral patients more frequently reported pre-hospital antibiotic use (231, 54.0%) than those self-referred (131, 26.7%, p<0.001). Fewer patients (131, 34.7%) reported antibiotic use during the high malaria transmission season than outside (232, 42.7%, p<0.001).

Microbiological diagnoses (malaria microscopy, blood culture, PCR of nasopharyngeal swabs) were available for 275/363 (75.8%) patients who reported pre-hospital antibiotic use. Of these, 113 (41.1%) were bacterial infections, and the remainder malaria (70, 25.5%), viral infections excluding HIV (85, 30.9%), and HIV (7, 2.6%) HIV.

AWaRe distribution of antibiotics

Overall, 424 antibiotics were reported by 363 patients: 263 (62.0%) belonged to the Access group, 159 (37.5%) to the Watch group and none to the Reserve group, while 2 (0.5%) unclassified antibiotics were reported. Watch antibiotics were more frequently reported by >14 year olds (72, 51.1%) than by 0-14 year olds (87, 30.7%, p<0.001) and by referrals (117, 42.2%) compared to self-referred patients (41, 28.1%, p=0.004). There was no difference in the proportion of Watch antibiotics used between the high and low malaria-transmission season (Table 2).

* Missing data in 1 patient

Antibiotics reported

Ampicillin or amoxicillin use was most reported (Access group, 137/424, 32.3% of all antibiotics reported). The most frequently used Watch antibiotics were ceftriaxone (114, 26.9% of all antibiotics reported) and ciprofloxacin (32, 7.5% of all antibiotics reported). Among antibiotics reported by referral patients (n = 277), ceftriaxone was recorded 100 times (36.1%) and ciprofloxacin 12 times (4.3%). Among antibiotics reported by self-referred patients (n = 146), ciprofloxacin was recorded 20 times (13.7%) (Table 3).
Table 3
Distribution of pre-hospital antibiotics used for severe febrile illness by referral status

Frequency of an antibiotic reported among patients referred from primary health centers is expressed as the number of this antibiotic divided by the total number of all antibiotics reported in referred patients (n = 277). Frequency of an antibiotic reported among self-referred patients is expressed as the number of this antibiotic divided by the total number of all antibiotics reported in self-referred patients (n = 146). Ampicillin or amoxicillin* is use of either ampicillin or amoxicillin

Of the reported antibiotics, 196 (46.2%) were intravenous versus 228 (53.8%) oral. Intravenous antibiotic use was not significantly different between 0-14 year olds (48.4%) and >14 year olds (41.8%, p=0.2) but more frequently reported among referrals (180, 65.0%) than those self-referred (15, 10.3%, p<0.001).

Discussion

Nearly 40% of patients presenting with acute fever to a referral hospital in rural Burkina, reported preceding antibiotic use; more than half of patients who were referred by a primary health care centre, and a quarter of self-referred patients. Nearly 60% of febrile patients with preceding antibiotic use and a microbiological diagnosis did not have a bacterial infection confirmed. While empirical first- or second-choice (Access) antibiotics were most frequently used, Watch antibiotics were used by 42% of patients referred from a primary health center. This is worrisome particular since ceftriaxone is not on the Burkina Faso medicine list for use in primary health centers and is recommended at this level only in case of a meningitis outbreak (which fortunately did not occur during our study period) (23). Moreover, Watch antibiotics accounted for 28% of
antibiotics used by self-referred patients, who presumably self-medicated with antibiotics obtained without prescription at private pharmacies or from informal drug sellers. Watch antibiotics use was not associated with severity or seasonality as there was no increased risk for patients admitted compared to those treated as outpatients nor during low-malaria transmission season compared to high-malaria transmission season. The high proportion of ceftriaxone – administered intravenously – among the Watch antibiotics reported by the referrals, but also the self-referred patients is of particular concern.

High and increasing use of Watch antibiotics has been observed in other low- and middle-income settings (6,24,25). To optimize antibiotic use, it is important to better understand the origins of and reasons why Watch antibiotics are used, both at primary health center level and without prescription at community-level. Our study illustrates the need to monitor antibiotic use among official and informal healthcare providers. Nationwide antibiotic consumption estimated from official sales data found that, in 2015, 75% of antibiotics consumed in Burkina Faso were Access and 24% Watch group, achieving the WHO target of at least 60% of antibiotics used to be Access antibiotics (14). This use of Watch antibiotics is lower than the proportion of Watch antibiotics reported in the present study, while we did not even include inpatient antibiotic use, where a higher proportion of Watch antibiotics can be expected. In comparison, the frequency of pre-hospital antibiotic use by febrile patients admitted to the Nanoro district hospital in 2012-2013 was lower (28.2%), and the proportion of Access antibiotics used was higher (45.9% amoxicillin or ampicillin vs 32.3% now and 35.1% trimethoprim + sulfamethoxazole vs 10.6% now) (18), further confirming the need to halt and reverse this high prevalence of Watch antibiotic use.

Despite ampicillin being the treatment of choice for patients with severe infectious diseases at primary health center level pending referral, it is increasingly ineffective against Enterobacterales. Indeed, most (90.5%) of non-Typhi Salmonella and 87.5% of Escherichia coli were resistant to ampicillin in Nanoro during 2012-2013 (18). This could explain (systematic) use of ceftriaxone when bloodstream infection is suspected in the absence of a microbiological testing. Rapid referral to the district hospital, where laboratory testing should be available as recommended in the WHO model list of essential in vitro diagnostics (26), is needed to prevent such overuse of Watch antibiotics. Because cephalosporin use has been associated to the emergence of beta-lactamase-secreting pathogens, particular caution must be taken to optimize its use (27). Integrating point-of-care CRP or procalcitonin tests at primary health center level, to differentiate between bacterial and non-bacterial fever, could be explored.

Some caution interpreting these findings is needed. First, the inclusion of outpatients during the second half of the study period might have resulted in some changes in the study population and pre-hospital antibiotic use. However, we observed no difference in the prevalence of antibiotic use, when comparing the two populations from both recruitment periods. Further, data about pre-hospital antibiotic use were missing for a quarter of patients. We included only patients presenting with severe acute fever, not representative of any illness episode in the community. Antibiotic use was collected via a survey, recalling use during two weeks before consultation or admission to the district hospital, potentially underestimating actual use. Whenever possible, reported antibiotic use was verified from referral forms (if referral from PHC), patient medical files (healthcare booklet), and antibiotic packaging or blisters. Dosage and duration of antibiotic used were not available and the final diagnoses at the district hospital may not correspond to those that had triggered prescription or self-medication within the two preceding weeks.
Conclusion

The frequent use of Watch antibiotics in primary health care centers and at community-level in rural Burkina Faso is concerning in a context of increasingly ineffective first-line antibiotics and increasing detection of beta-lactamase producing bacteria. It points to the need to set up antibiotic use monitoring and antibiotic stewardship in rural communities in low- and middle-income countries (LMIC), as over-the-counter or informal community-level antibiotic use can be very frequent in communities with limited access to hospital care. As no alternatives for the currently available Watch antibiotics are available nor affordable in many LMIC settings, it is imperative to act to avoid even more alarming levels of resistance in years to come.

WHO: World Health Organization

Declarations

Ethics approval and consent to participate

The PaluBac study protocol and an amendment to include pre-admission antibiotic use were approved by the Ethics Committee for Health Research of Burkina Faso (ref 1029/15 and 2017-01-001). Written informed consent was obtained from all included patients or their caretakers.

Consent for publication

All the patients included in the study or their caretakers gave their consents for publication.

Availability of data and materials

All data generated or analysed during this study are included in this published article and datasets used during the current study are available from the corresponding author on reasonable request.
Competing interests

The Authors declare that they have no competing interests

Funding

The authors received no specific funding for this work

Acknowledgments

We acknowledge all the Palubac study team and all study participants for their willingness to participate in this study. We are also thankful to the Palubac study staff, mainly the clinicians and nurses who participated in data collection. We thank all the Clinical Research Unit of Nanoro staff as well as the Nanoro district hospital staff for being part in some ways of the success of this study.
