Institute of Experimental Physics, Graz University of Technology, Petersgasse 16, A-8010 Graz, Austria/EU

ABSTRACT: We report on the spectroscopic investigation of lithium atoms and lithium dimers in their triplet manifold on the surface of helium nanodroplets (HeN). We present the excitation spectrum of the 3p ← 2s and 3d ← 2s two-photon transitions for single Li atoms on HeN. The atoms are excited from the 2S(Σ) ground state into Δ, Π, and Σ pseudodiatomic molecular substates. Excitation spectra are recorded by resonance enhanced multiphoton ionization time-of-flight (REMPI-TOF) mass spectroscopy, which allows an investigation of the exciplex (Li*–HeN) m = 1–3 formation process in the Li–HeN system. Electronic states are shifted and broadened with respect to free atom states, which is explained within the pseudodiatomic model. The assignment is assisted by theoretical calculations, which are based on the Orsay–Trento density functional where the interaction between the helium droplet and the lithium atom is introduced by a pairwise additive approach. When a droplet is doped with more than one alkali atom, the fragility of the alkali–HeN systems leads preferably to the formation of high-spin molecules on the droplets. We use this property of helium nanodroplets for the preparation of Li dimers in their triplet ground state (1^3Σg). The excitation spectrum of the 2^3Π←1^3Σg transition is presented. The interaction between the molecule and the droplet manifests in a broadening of the transitions with a characteristic asymmetric form. The broadening extends to the blue side of each vibronic level, which is caused by the simultaneous excitation of the molecule and vibrations of the droplet (phonons). The two isotopes of Li form ^6Li2 and ^7Li2 as well as isotope mixed ^6Li^7Li molecules on the droplet surface. By using REMPI-TOF mass spectroscopy, isotope-dependent effects could be studied.

INTRODUCTION

Helium nanodroplets (HeN) have attracted strong interest as superfluid nanocrystals for the efficient preparation of tailored molecules and clusters at ultracold temperatures. The spectroscopy of atoms on/in helium nanodroplets gives insight into the nature of interactions between a nanosized superfluid and single atoms. Moreover, the special properties of helium nanodroplets enable the formation of tailored molecules and offer a possibility to study complexes that can not, or only with great expense, be produced in the gas phase or in molecular beam experiments. An example is the preparation of alkali (Ak) metal dimers and trimers in their weakly bound high-spin configuration (triplet and quartet states, respectively) or even high spin clusters at low temperatures (0.37 K). The lowest electronic transitions (D1 and D2 lines) in Ak atoms on the surface of helium nanodroplets are well characterized. The D1 and D2 lines of Li atoms on the surface of HeN are an exception among the Ak–HeN systems because their main absorption peak is lower in energy than the free atom transition. This red-shift has its origin in bound–bound transitions from the ground state into the two 2P(Π) states. While excitation spectra of Rydberg states for Na, Rb, and Cs have been reported, less work has been done on the characterization of K–HeN and Li–HeN. Besides the D1 and D2 lines, only the 5p ← 4s transition in K–HeN and the 3s ← 2s transition in Li–HeN have been investigated.

For the assignment of excited states of Ak atoms on HeN, we use the pseudodiatomic model (Hund’s case a notation is appropriate). Because of the presence of the droplet, the symmetry of the atomic system is broken and only the projection of the atomic orbital angular momentum L onto the intermolecular axis (i.e., Λ), which is defined by the connection between the droplet center and the Ak nucleus, remains a conserved quantity. In the case of Li, spin–orbit (SO) splitting can be neglected (e.g., SO splitting for the 2P state: 0.34 cm⁻¹). For two-photon excitations, transitions from the Li–HeN 2S(Σ) ground state into Δ, Π, and Σ molecular substates are allowed. The fragility of systems formed by helium nanodroplets with molecules on their surface enhances the formation of weakly bound complexes because the binding energy, which is gained during the formation of the molecule, is released into the droplet. This excess energy could destroy the complex formed.
by the molecule and the droplet. Hence, the weakly bound alkali dimers in the triplet manifold have a higher probability of survival than the singlet molecules, and the helium droplets act as a filter for Ak dimers in the triplet manifold. Triplet bands of Nα,β4,4, Kα,β,γ2,6–28 and Cα,β29 have been studied in detail. For Li2 on HeN, only the 1Πl ← 1Σu transition, which is a bound-free transition, has been reported so far. The orientation of the ground state Li dimers for the two different spin configurations (1Σu+ and 1Σu− state) with respect to the droplet surface has been investigated theoretically for small HeN (for N up to 30), where it was found that the singlet molecule is perpendicular and the triplet one is oriented parallel to the droplet’s surface.30 In contrast to the Li2−HeN system, triplet bands of free Li2 molecules have been studied extensively experimentally31 as well as theoretically.32 The most accurate experimental data have been recorded by perturbation facilitated optical–optical double resonance (PFOODR) spectroscopy.31 This allows a detailed comparison between molecules on HeN and free molecules, which reveals insight into the interaction between the superfluid droplet and the molecule on its surface.

In the first part of this article, we report on the investigation of the two-photon 3p ← 2s and 3d ← 2s transitions in Li−HeN by resonance enhanced multiphoton ionization time-of-flight (REMPI-TOF) spectroscopy. Pseudodiatomic molecular substates are identified on the basis of the observed abundance of exciplexes because the exciplex formation process depends on Λ of the molecular substate. Calculations based on a pairwise additive approach support our assignment. In the second part of this article, we report on the investigation of the 2Πu ← 1Σu+ transition of the Li dimer on HeN. Vibronic states could be resolved and the low mass of the Li atom in combination with the REMPI-TOF technique allows to study the band for all three Li isotopomers, 6Li2, 7Li2, and 6Li7Li, as well as an investigation of their interaction with the droplet.

## EXPERIMENTAL SECTION

A detailed description of the experimental setup can be found in refs 33 and 34. High purity helium gas is cooled down to a temperature of T0 = 15 K and expanded through a d0 = 5 μm nozzle under a pressure of p0 = 60 bar into vacuum. These conditions lead to a subcritical supersonic jet expansion of the He gas and consequently to the formation of helium droplets, where the droplet size follows a lognormal distribution. The source conditions lead to a distribution maximum (N0,40) at N0,40 = 6000 He atoms,35,36 which corresponds to a droplet radius of R0,40 = 40 Å. After production, the helium droplet beam is guided into another vacuum chamber where it is doped with Li by passing through a resistively heated pickup cell. The pickup statistic obeys a Poisson distribution.35 The process depends on the vapor pressure within the pickup cell, which is controlled by the cell temperature. At the used temperature of T ≈ 350 °C, Li atoms as well as Li dimers are present on the droplets.

The excitation spectra have been obtained by resonance enhanced multiphoton ionization time-of-flight (REMPI-TOF) spectroscopy. A tunable pulsed dye laser (Lambda Physik FL 3002) is used to access Li−HeN and Li2−HeN transitions. To cover the spectral range, three different laser dyes have been used. The Li1−HeN dimer spectrum has been obtained by resonant two-photon ionization, using Coumarin 2 (0.3 mJ) and Stilbene 3 (0.5 mJ). The Li−HeN complexes have been excited via a two-photon scheme (without a resonant intermediate state) with DCM (5.2 mJ) and ionized with a fraction (0.6 mJ) of the XeCl pump laser radiation (Radiant Dyes RD-EXC-200 XeCl laser, 26 ns pulse duration, 100 Hz).

## RESULTS

### Spectroscopy of Li Atoms on HeN

In this section, we discuss the two-photon 3p ← 2s and 3d ← 2s transitions in Li−HeN. Because of the small size of the Li ion core, states with l > 0 lie energetically very close together in the lithium atom (these states have a core nonpenetrating character37). Only the nS states are significantly shifted with respect to the hydrogenic term energy. Note that because of the l < n condition for the orbital angular momentum quantum number l the 3D state investigated here is a special case among the nD Li−HeN Rydberg series because it does not overlap with an F state.

The two-photon excitation spectrum of the 3p ← 2s and 3d ← 2s transitions in Li−HeN is depicted in Figure 1. The ion signal for 6Li−He (red, x9, smoothed signal only), 7Li−He (green), 6Li−He2 (blue), and 7Li−He2 (black) is monitored as a function of the excitation laser wavenumber (multiplied by two) with a time-of-flight mass spectrometer. The 3P and 3D free atom states at 30 925 cm−1 and 31 283 cm−1 are shown as vertical black lines.

![Figure 1](https://example.com/figure1.png)

**Figure 1.** Two-photon excitation spectrum of Li−HeN. The spectrum is obtained by monitoring the 6Li−He (red, x9, smoothed signal only), 7Li−He (green), 6Li−He2 (blue), and 7Li−He2 (black) ion yield as a function of the excitation laser wavenumber (multiplied by two) with a time-of-flight mass spectrometer. The 3P and 3D free atom states at 30 925 cm−1 and 31 283 cm−1 are shown as vertical black lines.
states a large fraction of the atoms desorb without attached helium atoms. In contrast, the ionization via states with \( \Lambda > 0 \) is always accompanied by an abundance of \( \Lambda = 0 \) complexes in the time-of-flight mass spectra. Hence, we attribute the pronounced peak at \( (31 016 \pm 2) \text{ cm}^{-1} \), full width at half-maximum (fwhm) = \( (43 \pm 3) \text{ cm}^{-1} \) (as monitored on the \( ^7 \text{Li}^-\text{He}_2 \) mass) to the 3P(\( \Pi \)) state. We call this approach for the assignment of excited states based on the exciplex formation process the "exciplex approach" in the following. In contrast, the signal in between the 3P(\( \Pi \)) and the 3D line is only visible in the \( ^7 \text{Li}^-\text{He} \) ion signal; hence, we attribute this part of the spectrum to the onset of the 3P(\( \Sigma \)) state. The structure of the signal, which correlates to the 3D molecular substates, is similar to the signal obtained for the \( \text{Rb}^-\text{He}_2 \) system in ref 20. The state related to the peak at \( (31 278 \pm 5) \text{ cm}^{-1} \), fwhm = \( (52 \pm 7) \text{ cm}^{-1} \) (as monitored on the \( ^7 \text{Li}^-\text{He}_2 \) mass) is accompanied with a high probability for the formation of exciplexes. Hence, we assign this peak to the 3D (\( \Delta \)) state. It is remarkable that this state appears almost unshifted with respect to the free atom transition at \( 31 283 \pm 10 \text{ cm}^{-1} \), which has to be taken into account when excitation spectra are compared to free atom transitions, the 3D(\( \Delta \)) potential has a binding character and its minimum lies about \( (-15 \pm 7) \text{ cm}^{-1} \) below the asymptotic 3D energy. This demonstrates a weak attractive interaction of the Li atom in the 3D(\( \Delta \)) state with the droplet. Similar signals have been observed in ref 17 for the \( \text{Na}^-\text{He}_2 \) 4P \( \leftrightarrow \) 3S and 4D \( \leftrightarrow \) 3S transitions, which compare to the presented \( \text{Li}^-\text{He}_2 \) transitions. Therein, increased exciplex formation upon excitations into states associated with high \( \Lambda \) was observed close by the free Na atom lines. In the \( ^7 \text{Li}^-\text{He} \) ion signal, the blue shoulder of the 3D(\( \Delta \)) peak extends to much higher wavenumbers than in the \( ^7 \text{Li}^-\text{He}_2 \) detected spectrum, and it is followed by a second peak at \( (31 536 \pm 10) \text{ cm}^{-1} \), which we attribute either to a part of the 3D (\( \Pi \)) or (\( \Sigma \)) state.

To simulate the spectra, we use the Orsay–Trento density functional\(^{39}\) as implemented in the code by F. Dalfovo, with modifications by K. K. Lehmann and R. Schmied.\(^{40–42}\) The interaction between the helium droplet and the alkali atom is introduced by a pairwise additive (PWA) approach. To obtain the radial density profile of the ground state, the lithium–helium potential of Patil\(^{43}\) is used. For the excited states, the curves of Pascale represent the set of \( ^7 \text{Li}^-\text{He} \) interactions of the electronic states relevant for this work.\(^{44,45}\) An effective coordinate \( z_L \) is introduced as the distance between the center of mass of the droplet and the lithium atom. By convoluting the density with the above pair potentials, we obtain the pseudodiatomic potentials shown in Figure 2. We accounted for the correct projection of the angular momentum on the helium–lithium axis by means of Wigner rotation matrices, following ref 13 and transforming the Hamiltonian in a diagonal shape. Spin–orbit coupling can be neglected, as the interaction with the droplet is much larger. In the frozen droplet picture, assuming a fast desorption of the lithium atom upon excitation,\(^{24}\) Franck–Condon factors (FCFs) are calculated with the help of BCONT 2.2 by LeRoy\(^{46}\) for bound-free transitions of the pseudodiatomic molecule. The majority of the \( \text{Li}^-\text{He}_2 \) systems are in their vibronic ground state (\( \nu = 0 \)) before the excitation.

The calculated FCFs are shown in Figure 3. It can be seen that our approach overestimates the blue shift of the excited states. Such large blue shifts on the order of several thousand wavenumbers have already been observed for calculations of excited states of \( \text{Na}^-\text{He}_N \) in ref 17, where it was shown that the PWA approach works best at states with low principal quantum number \( n \). In addition to the PWA approach, for \( \text{Na}^-\text{He}_N \) a perturbative configuration interaction (PCI) approach was used, where the helium dopant interaction is introduced by a perturbation rather than a pair potential. The PCI model shows a better agreement with the experimental spectra than the PWA approach; unfortunately, this model is not yet parametrized for lithium. Although our potential energy curves (see Figure 2) for the 2S(\( \Sigma \)), 2P(\( \Pi \Sigma \)), and 3S(\( \Sigma \)) reproduce the results of other calculations,\(^{13,24}\) the spectrum for the 3P and 3D states is far off the experimental one. However, the calculated theoretical
spectrum for the transition from the ground state into the $3Σ(\Sigma)$ state has a maximum at $\sim 27,880 \text{ cm}^{-1}$, which matches the experimental peak maximum ($\sim 27,820 \text{ cm}^{-1}$) very well as can be seen from Figure 4 in ref 24. The difference between the experimental peak maximum ($\sim 27,820 \text{ cm}^{-1}$) and the theoretical peak maximum ($\sim 27,880 \text{ cm}^{-1}$) is due to several approximations in the PWA theory and experiment for the 3P and 3D spectra is expected to be enhanced by the present laser photons. This could explain the absence of a prominent peak corresponding to the weakly bound $^7\text{Li}^-\text{H}_2\text{O}$ ($m/z = 25$) van der Waals complex, which is in contrast to the findings in ref 49. We find no evidence for the

The above discussion reveals that a more sophisticated approach is needed to describe higher excited states of Li–HeN accurately. Different approaches have been presented recently$^{48}$ where the best results for Li–HeN have been obtained with the methods developed by the Barranco group.$^{14,24}$ However, the energetic ordering as described above for the 3P(\Pi), 3P(\Sigma), 3D(\Delta), 3D(\Pi), and 3D(\Sigma) states is reproduced by our calculations. According to the PWA approach, the 3P(\Pi) state lies energetically lower than the 3P(\Sigma) state, and the 3D(\Delta) state is the energetically lowest among the three 3D molecular substates, which is in agreement with our assignment within the exciplex approach. Despite the differences between calculation and experiment, we think that the expected energetic ordering of excited states confirms our interpretation within the exciplex approach.

For the $3s \leftarrow 2s$ transition, an isotope shift for the two different Li isotopes has been observed.$^{24}$ As can be seen from the excitation spectrum in Figure 1, we do not observe a significant isotope effect within the accuracy of our data.

Figure 4 shows the time-of-flight mass spectrum as obtained, while the laser is scanned across the two-photon transitions (Figure 1). The highest signal is detected at the mass-to-charge ratio $m/z$ corresponding to bare $^6\text{Li}$ and $^7\text{Li}$ ions. The intensity of the peaks reflects the natural abundance of the two Li isotopes ($^6\text{Li}$, 7.4%; $^7\text{Li}$, 92.6%). These two Li mass peaks are followed by peaks originating from Li–He, Li–He$_2$, and Li–He$_3$ in steps of 4 amu ($^4\text{He}$). Because of the high photon density and the presence of the 308 nm light, Li dimers ($^6\text{Li}_2$, $^7\text{Li}_2$, and $^7\text{Li}$(\text{LiOH})) are also observed in the mass spectrum. At higher $m/z$ ratios (for $m/z > 16$ the signal is multiplied by a factor of 20), two prominent peaks are observed. These peaks are related to residual water, which was present in our chamber during the experiment. We attribute the peaks at $m/z = 24$ and $m/z = 31$ to the products of an oxidative hydrolysis of $^7\text{LiOH}$ and $^7\text{Li}$($^7\text{LiOH}$), respectively, which are produced upon a reaction with water in the helium droplet.$^{50}$ Because of the resonant excitation of an intermediate state, the reaction may be enhanced by the present laser photons. This could explain the absence of a prominent peak corresponding to the weakly bound $^7\text{Li}^-\text{H}_2\text{O}$ ($m/z = 25$) van der Waals complex, which is in contrast to the findings in ref 49. We find no evidence for the

![Figure 4. Time-of-flight mass spectrum as obtained while the laser is scanned across the two-photon transitions, which is shown in Figure 1. The most intense ion signal is detected for $^6\text{Li}$ and $^7\text{Li}$ ions. Peaks in steps of 4 amu are related to Li ions with attached helium atoms. In addition to Li dimers, which are formed on the droplets, also complexes of Li, Li$_2$, and residual water, which is present in the vacuum chamber, are observed in the mass spectrum.](image)

![Figure 5. Excitation spectrum of the $2^3\Pi_g (\nu') \leftarrow 1^3Σ_u^+ (\nu' = 0)$ triplet transitions of Li dimers on the surface of helium nanodroplets (a). The spectrum is obtained by resonant two-photon ionization spectroscopy. The spectra of all three isotopomers $^6\text{Li}_2$ (red), $^7\text{Li}^-\text{Li}$ (green), and $^7\text{Li}_2$ (blue) are shown. Calculated Franck–Condon factors are shown (in arbitrary units) as vertical bars and scaled to the $\nu' = 1$ peak (b).](image)
formation of Li clusters (i.e., Li$_{n+2}$) at our source conditions. This is in agreement with other experiments as discussed in ref 5. The absence of these complexes is related to the high formation energies of lithium clusters, which are significantly higher than those of the heavier Alk clusters and have been investigated in detail on/in helium nanodroplets. We think that the production of Li clusters will require larger helium droplets ($N > 10^5$) produced by source conditions with lower temperatures in the supercritical expansion regime.

**Spectroscopy of Li Dimers on HeN**. The excitation spectrum of Li dimers in the range between 21 250 and 24 000 cm$^{-1}$ is shown in Figure 5a. The spectrum was obtained by resonant two-photon ionization spectroscopy. The observed vibronic transitions are identified as $2\Pi_u^+(\nu') \rightarrow 1\Sigma_u^+(\nu = 0)$. The ion yield for $m/z = 12$ (6Li$_2$), 13 (6Li-7Li), and 14 (7Li$_2$) was monitored as a function of the dye laser wavenumber. Hence, the excitation spectra of all three isotopomers are observed. The composition of the molecules on the droplets is 85.71% 6Li$_2$, 13.71% 6Li-7Li, and 0.55% 7Li$_2$. Because of the low abundance of 6Li$_2$, the ion signal obtained for 6Li$_2$ is very weak and was smoothed and multiplied by a factor of 10. The recorded spectrum was fitted with a sum of asymmetric two-sigma functions

$$L(\nu) = I (1 + e^{(\nu-\nu_I+\nu_0)/2}/\nu_0)^{-1} [1 - (1 + e^{(\nu-\nu_0-\nu_I)/2}/\nu_0)]^{-1}$$

(1)

We identify the position of the recorded peaks at the wavelength where the second derivative of eq 1 has a maximum for each set of fit parameters. This wavelength corresponds to the onset of the rising edge within a few wavenumbers (depending on the signal-to-noise ratio) and hence to the origin of the vibronic band. The results are compared to the calculated positions of the vibronic levels. The determined positions lie within an interval of 0 to +4 cm$^{-1}$ for 6Li$_2$ ($\nu' = 1-8$), −5 to +4 cm$^{-1}$ for 6Li-7Li ($\nu' = 1-8$), and 0 to +11 cm$^{-1}$ for 7Li$_2$ (\nu' = 1-4) around each calculated value. Higher vibronic states and the 4Li$_2$-HeN spectrum have a larger uncertainty due to the relatively low signal. The fit procedure does not reproduce accurately the calculated position of the origin of the $\nu' = 0$ level for 6Li$_2$ (the wavenumber for 6Li-7Li differs by −12 cm$^{-1}$ from the calculated value). In this case, we identify the position with the onset of the rising edge at 21 707 cm$^{-1}$ (10 cm$^{-1}$ below the calculated value). The spectra in the upper panel in Figure 5 appear to be superimposed by a large nonresonant background signal, which reaches from 21 250 to 23 000 cm$^{-1}$. At the applied laser pulse energy, resonance enhanced two-photon ionization may be expected. According to ref 57, the ionization potential of free Li$_2$ lies at $T_e = 41.496 \pm 4$ cm$^{-1}$, and another $\nu_0$ state, $2\Sigma_h^+$ may enhance the broad two-photon ionization signal.

| $T_e$      | 21623 (9)        | 21621 (6)            | 21601 (44)       | 21601 (44)       | 29840.5          | 29840.5          |
| $T_e'$     | 29837 (9)        | 29844.7              | 29836 (6)        | 29817 (44)       |                  |                  |
| $\omega_e$ | 189.7 (4.7)      | 188.66               | 201 (3.3)        | 196.36           | 215 (41)         | 204.2            |
| $\omega_{\nu_8}$ | 1.15 (0.5) | 1.20                | 1.7 (0.4)        | 1.29             | 2.6 (8)          | 1.37             |

$^a$Only vibronic transitions where the rising edge could be clearly identified are included in the fit procedure. 6Li$_2$, $\nu' = 0$; 6Li-7Li, $\nu' = 0$; 6Li$_2$, $\nu' = 0$–4. Parameters are given in cm$^{-1}$, and one standard deviation uncertainties are given in parentheses. Parameters for 6Li-7Li are calculated from the parameters given by Li et al.$^{61}$
Experimental high resolution data and theoretical calculations are available for the $2\Pi_g$ state. This allows a detailed comparison between the spectroscopy of free molecules and molecules on the droplet. The most accurate experimental data have been obtained by perturbation facilitated optical–optical double resonance (PFOODR) spectroscopy,\(^\text{31}\) where for the $2\Pi_g$ state all three isotopomers of the Li dimer have been investigated.\(^\text{30–61}\) In order to use helium nanodroplets in future experiments as a matrix for the electronic spectroscopy of tailored molecules on their surface, we are interested in the accuracy of spectroscopic constants, which can be extracted from their spectra. Therefore, we determine the molecular constants for the sake of comparison with the literature values of free molecules. In Table I, we summarize the molecular constants as obtained from a least-squares fit of the observed band positions to the standard expression\(^\text{62}\)

$$T(\nu') = T + a_0\left(\sqrt{\nu'} + \frac{1}{2}\right) - a_1x_0\left(\sqrt{\nu'} + \frac{1}{2}\right)^2$$  \hspace{1cm} (2)

The obtained results are compared to experimental results from Xie and Field\(^\text{63}\) (for $^7\text{Li}_2$) and Li et al.\(^\text{64}\) (for $^7\text{Li}_2$). The parameters for $^7\text{Li}_2$ are calculated from the $^7\text{Li}_2$ parameter by a multiplication with the isotope factor $\rho = (\mu'/\mu)^{1/2}$, where $\mu'$ and $\mu$ are the reduced masses of $^7\text{Li}_2$ and $^7\text{Li}_2$, respectively. This is a valid approach within the Born–Oppenheimer approximation, where the three $^7\text{Li}_2$ isotopomers have identical potential curves. Although Born–Oppenheimer breakdown effects are significant in $^7\text{Li}_2$\(^\text{61}\) they can be neglected within the accuracy of our results. A direct determination of $T_c$ from our data is not possible since we only have access to the triplet molecule. Hence, we calculate $T_c$ from $T$ in eq 2 by adding a constant offset of 8213.8, 8215.2, and 8216.4 cm$^{-1}$ for $^7\text{Li}_2$, $^7\text{Li}_2$, and $^7\text{Li}_2$, respectively, which corresponds to the absolute energy of the $^1\Sigma_u^+(\nu' = 0)$ state.\(^\text{63}\) The molecular parameters listed in Table I demonstrate that parameters deduced from lithium molecules on the surface of helium nanodroplets agree well with free molecule parameters (within the $2\sigma$ uncertainty interval).

**SUMMARY AND CONCLUSIONS**

We have shown that two-photon spectroscopy of Li–He$_N$ offers a possibility to access Li–He$_N$ Rydberg states without UV lasers. We were able to assign the $3p \leftrightarrow 2s$ and $3d \leftrightarrow 2s$ transition of Li atoms on helium nanodroplets by using two different methods. Within the pseudodatotic model, the states split into the $3P$ ($\Pi, \Sigma$) and $3D$ ($\Delta, \Pi, \Sigma$) different molecular substates. The first approach (exciplex approach) used for the assignment exploits the fact that the exciplex formation process depends on the $\Lambda$ quantum number of the intermediate state. In the second part of the discussion of Li–He$_N$ we present calculations for the description of the observed transitions. Li–He$_N$ potentials are generated by using a pairwise additive approach and assuming a frozen helium density that interacts with the excited dopant. The potential energy curves support the observed ordering of the states. The obtained Franck–Condon factors of the bound free transitions overestimate the blue shift of the transitions and reveal the necessity of more sophisticated theoretical models for the accurate description of excited Li–He$_N$ states, which are capable of including quantum effects,\(^\text{4,24}\) which are non-negligible for lithium, as well as configuration interactions of the energetically close P and D states. As the lightest of the alkali metals, lithium is another interesting candidate for a detailed study of the corresponding alkali–He$_N$ Rydberg complex, so far investigated for Na–He$_N$,\(^\text{6,17}\) Rb–He$_N$,\(^\text{19,20}\) and Cs–He$_N$.\(^\text{19,23}\) Recording the blue or red shifts of Rydberg states on droplets with respect to the free atom energies may provide further insight into the shielding effects of the helium droplet as obtained from our recent Rydberg–Ritz analysis.\(^\text{19}\)

In addition to the spectroscopy of Li–He$_N$, we show for the first time a spectrum of a bound–bound transition of Li$_2$ molecules on the surface of He$_N$. The observed bands are identified as $2\Pi_g (\nu' = 0) \rightarrow 1\Sigma_u^+ (\nu' = 0)$ transitions. The REMPI-TOF technique allows to study all three isotopomers ($^6\text{Li}_2$, $^7\text{Li}_2$, and $^7\text{Li}_2$) of the Li dimer simultaneously. The spectrum comprises a series of vibronic transitions, broadened by the influence of the droplet. The vibronic transitions could be followed from $\nu' = 0$ to $\nu' = 11$ for the $^7\text{Li}_2$ isotope. Our investigation of Li$_2$ shows that despite the interaction between the molecule and the droplet, helium droplet isolation spectroscopy can serve as a tool to test ab initio molecular potentials of electronically excited states of species on the droplet surface. In future experiments, we plan to use our insights gained from the Li–He$_N$ experiments presented in this article and combine the Li atom with alkaline-earth atoms, a complex that can not be formed easily in the gas phase. Helium droplet isolation spectroscopy will provide a versatile tool to study these species and to test the corresponding ab initio potentials.
