Unconfined granular flows along an inclined plane are investigated experimentally. During a long transient, the flow gets confined by quasi-static banks but still spreads laterally towards a well defined asymptotic state following a non-trivial process. Far enough from the banks a scaling for the depth averaged velocity is obtained, which extends the one obtained for homogeneous steady flows. Close to jamming it exhibits a crossover towards a non local rheology. We show that the levees, commonly observed along the sides of the deposit upon interruption of the flow, disappear for long flow durations. We demonstrate that the morphology of the deposit builds up during the flow, in the form of an underlying static layer, which can be deduced from surface velocity profiles, by imposing the same flow rule everywhere in the flow.

PACS numbers:

Geophysical granular flows such as pyroclastic flows or debris avalanches self-channelize, forming a coulee surrounded by static banks, until they come to arrest and form a deposit with levee/channel morphology. Recent laboratory experiments involving short time interruption of a localized flow of dry granular material have reproduced such deposit morphology and underlined the need for a deeper knowledge of the rheology. Flows down an incline provide a natural configuration for studying the rheometry of dense granular media. In the case of homogeneous flows, experiments have shown that there is a minimum thickness \( h_{\text{stop}}(\theta) \) below which no flow occurs and a maximum one \( h_{\text{start}}(\theta) \) above which static layers spontaneously destabilise. Later it has been shown that the depth averaged velocity \( \bar{u} \) is related to the thickness \( h \) by the flow rule:

\[
\frac{\bar{u}}{\sqrt{gh}} = \beta \frac{h}{h_{\text{stop}}(\theta)} + \alpha, \tag{1}
\]

where \( g \) is the gravity, leaving unclear the dependance of the non-dimensional parameters \( \alpha \) and \( \beta \) on both the kind of grains and the covering of the incline. For a flow of glass beads down an incline covered with glued beads, \( \alpha = 0 \) and the flow rule is consistent with a local rheology. This rheology has been validated in various flow configurations, including non-steady and non-uniform flows as well as flows on erodible ground and was recently extended to three dimensions. However, it does not verify \( \bar{u}(h_{\text{stop}}) = 0 \) and hence does not describe the flow arrest, where non local effects are expected to become significant. Requiring this last condition imposes \( \alpha = -\beta \), a situation actually reported in the case of unconfined flows. Hence, it is of primary importance, both for practical and fundamental reasons to investigate further the situation where flowing and static regions coexist.

In this letter, we study experimentally an unconfined flow down an incline. The flow indeed self-channelizes

\[
\tan \theta = \tan \theta^\infty + (\tan \theta^0 - \tan \theta^\infty) \exp (-h/\alpha d), \tag{2}
\]

within static banks which may evolve freely. Our main goals are to characterise the rheology and dynamics of the flow close to jamming, and its relation to the morphology of the deposit when the flow stops.

Set-up – The experimental setup is sketched on Fig. (a). A \( 60 \times 300 \text{ cm}^2 \) plane, covered with sand paper of average roughness about 200 \( \mu \text{m} \), is inclined at an angle \( \theta \) ranging from 24° to 34°. The granular material consists of a slightly polydisperse mixture of spherical glass beads of diameter \( d = 350 \pm 50 \mu \text{m} \) and density \( \rho = 2500 \text{ kg m}^{-3} \). Grains are released from a reservoir located at the top of the plane by opening a gate of adjustable height and width. To produce homogeneous flows, the whole plane width is used, but for unconfined flows the gate width is reduced to 5 cm and the width of the plane is always larger than that of the avalanche. For the present set up, \( h_{\text{start}}(\theta) \) and \( h_{\text{stop}}(\theta) \) obey (Fig. (b)):...
with \( \alpha = 3.2, \theta_{\text{stop}}^\infty = 22.5^\circ, \theta_{\text{start}}^\infty = 23.0^\circ, \theta_0^\text{stop} = 33.6^\circ, \) and \( \theta_0^\text{start} = 35.6^\circ. \) The mass flow rate \( Q \) is measured at the end of the plane, where the grains fall inside a reservoir resting on a scale. During all experiments, some of which lasted up to 5 hours, \( Q \) fluctuated by less than 2%. A 572 \times 768 pixels camera positioned at the vertical of the plane is used to acquire images of the flow at 25 Hz. The local flow thickness \( h \) is measured using the deviation of a laser sheet inclined at \( \sim 5^\circ \) over the layer. The measured sensitivity (\( \sim 60 \mu \text{m} \)) is smaller than the grain size thanks to the averaging across the beam width (10mm) along \( x. \) About 10% of the grains are dyed in black and the velocity of the surface grains, \( u_s, \) is measured using a particle-imaging velocimetry algorithm. In all experiments the spanwise velocity component is found to be smaller than the resolution (2 mm/s).

Transverse spreading & self-channelization – Upon release of the grains, an avalanche front propagates down the plane at a constant velocity, leaving behind it a streamwise flow uniform in the \( x \)-direction (Fig. 1a). Plot-

Fig. 2(a) displays thickness profiles at successive time steps, after the front has reached the downstream extremity of the incline – typically after 100 s. It shows that the flow widens while the thickness profiles bend progressively. The central flow thickness converges rapidly toward an asymptotic value \( H_\infty(\theta, Q) \), whereas its width converges to an asymptotic value \( W_\infty(\theta, Q) \) with a much larger relaxation time (Fig. 2(b)). When preparing a flow of width larger than \( W_\infty \) by increasing the flow rate, and returning to the initial flow rate, the width decreases back to \( W_\infty \). This shows beyond any doubt the selection of an asymptotic steady state. Both \( W_\infty \) and \( H_\infty \) are observed to increase with the flow rate \( Q \). The aspect ratio \( H_\infty/W_\infty \) turns out to be independent of \( Q \) and slightly decreases with \( \theta \) (Fig. 2(c)).

Fig. 2(d) shows the transverse structure of the flow: an inner flowing region \((u = 0)\) flanked by two static banks \((u = 0)\) of width approximately 5 mm. These banks forms due to a strong increase of friction on the side of the layer, as the thickness \( h \) vanishes and thus \( \mu \) tends to \( \mu_0 = \tan \theta_0 \) (eq. 3)). Once the banks are formed, their external sides are so steep that the free surface angle \( \tan \Phi \equiv (\tan^2(\theta) + (\partial_y h)^2)^{1/2} \) becomes significantly larger than the plane angle \( \theta \) (Fig. 2(d)) allowing transverse displacements. Indeed, the banks are outside the metastable band \([h_{\text{stop}}, h_{\text{start}}]\) during the spreading phase and converge toward it in the asymptotic state. The flow is hence divided into a central flow region uniform in the \( y \)-direction – the ratio of the transverse to the vertical diffusion of momentum \( h^2/W^2 \approx 10^{-4} \) – and the banks dominated by three-dimensional effects. In both regions, inertial terms \( u_s \partial u_s/\partial y \approx hu_s^2/W^2 \approx 10^{-3}g \) are small.

Flow rule – The flow rule is first determined using homogeneous steady flows covering the total width of the plane (Fig. 3h, \( \Delta \)). For \( h/h_{\text{stop}} > 2 \) it is well described by eq. 11 with \( \alpha = 0 \) and \( \beta = 0.134 \) assuming \( \bar{u}/u_s = 3/5 \) (see below). For \( h/h_{\text{stop}} < 2 \), there is a systematic deviation towards lower \( u_s/(gh)^{1/2} \) values. However smaller thicknesses can not be further investigated in homogeneous flows. On the contrary self-channelized flows are naturally very thin and give access precisely to that range of thickness. Fig. 3h (●) shows data collected near the centerline of the flow, where the flow has been shown above to be uniform in the transverse direction. 

\[ Q \equiv (\tan \theta_0 \approx 0) \] during the spreading phase and converge toward it in the asymptotic state. The solid lines show \( H_{\infty} \) and \( W_{\infty} \) as a function of the slope angle, for flow rates \( Q \) ranging from 3 g/s (\( \Delta \)) to 30 g/s (\( \bullet \)). (d) Velocity \( u_s(y) \) (solid line) and thickness \( h(y) \) (dashed line) profiles for \( \theta = 25^\circ, Q = 25 \text{ g}, s^{-1} \) and \( t = 150 \text{ s} \). (e) Thickness vs. local slope \( \Phi \) inside the quasi-static banks (\( \circ \)): \( t < 2000 \text{ s}, (\bullet) \): asymptotic state. The solid lines show \( h_{\text{stop}} \) and \( h_{\text{start}} \).

configuration.

We now briefly discuss its relation to the locality of the rheology. For a large enough thickness, the flow rule obeys eq. (4) with \( \alpha = 0 \) and is consistent with a local rheology [4]: when the shear stress \( \tau \) depends on the shear rate \( \dot{\gamma} \) at the considered point only, it follows from dimensional analysis – assuming a small transverse shear stress as suggested by the flatness of the transverse velocity profiles – that the rheology can be expressed under the non-dimensional form

\[
\frac{\tau}{\mu(I)} \approx \frac{d(P/\rho)^{1/2}}{\mu(I)}
\]

with \( I = \dot{\gamma}d/(P/\rho)^{1/2} \), where \( d \) is the grain diameter, \( P \) the pressure and \( \rho \) the density. Integrating this last relation leads to a scaling law for the depth averaged velocity \( \bar{u}(h, \theta) = A(\theta)h^{3/2} \), which is indeed satisfied by eq. (4), when \( \alpha = 0 \). For a small thickness the flow rule eq. (4) clearly displays a violation of the local rheology close to jamming, which is confirmed by the measurement of the ratio of the depth averaged velocity \( \bar{u} \) – measured with the avalanche front velocity in the homogeneous flow case – to the surface velocity \( u_s \) (Fig. 3). For large \( h/h_{\text{stop}} \) values, \( \bar{u}/u_s = 3/5 \) which is consistent with Bagnold-like profile deriving from a local rheology [2]. Close to jamming transition, \( \bar{u}/u_s \) decreases to 1/2 in agreement with numerical findings [2] of a transition toward a linear velocity profile. Note that the above analysis suggests that \( \beta/h_{\text{stop}}(\theta) \) shall not depend on the covering of the incline whereas \( \tilde{\beta}/h_{\text{stop}}(\theta) \) and of course \( h_{\text{stop}} \) could. Finally from conservation of mass, one expects a linear relationship between \( Q \) and

\[
Q_{\text{stop}} = \rho g^{1/2} H_{\text{stop}}^{5/2} (H_{\infty}/h_{\text{stop}} - 1),
\]

using eq. (4). This relation is closely verified experimentally (Fig. 3) and suggests to describe the flow in a shallow water approximation. However, let us mention that neither the asymptotic state (its bended shape but also the selection of the aspect ratio \( H_{\infty}/W_{\infty} \)) nor the temporal scalings of \( W(t) \) and \( H(t) \) can be simply predicted following such an approach. Hence we shall postpone this analysis as well as a full three-dimensional analysis to a forthcoming paper. Note that the complete set of shallow water equations is solved in [11].

Banks – In the previous section, we investigated the flow rule near the centerline of the flow. No such scaling is a priori expected close to the static banks. Indeed as seen on Fig. 4(b), when acquiring data moving away from the centerline, no scaling is observed and \( u_s/(gh)^{1/2} \) is systematically underestimated. A possible explanation of such a deviation from the otherwise scaling is the extension of the static zone below the flowing grains. In order to verify such an hypothesis, we have performed

![FIG. 3: (a) Flow rule \( u_s/(gh)^{1/2} \) vs \( h/h_{\text{stop}} \): (Δ) data for steady homogeneous flows, (●) data obtained in the central – uniform – part of unconfined flows. Each point is an average over different realizations and the corresponding statistical error bars are reported. The solid (resp. dashed) line is the best fit by eq. (4) (resp. eq. (4) with \( \alpha = 0 \)). (b) Average to surface velocity ratio \( \bar{u}/u_s \) vs. \( h/h_{\text{stop}} \) for steady homogeneous flows. (c) Scaling of the asymptotic height with the flow rate: \( Q_H = \rho g^{1/2} H_{\infty}^{5/2} (H_{\infty}/h_{\text{stop}} - 1) \) as a function of \( Q \), for \( \theta \) ranging from 25° (Δ) to 28° (●).](image1)

specific experiments.

One first conducts an experimental run using white grains. After a few minutes, the flow is stopped and a deposit forms. The white grains of a small slice across the deposit are removed and replaced by black grains of the same material. The flow is then started again at the same flow rate. At the surface, the black grains are washed out by the incoming white grains except in the static borders. After a few minutes, the flow is interrupted again. Using a brush, the white grains are removed very cautiously layer after layer in the region of the slice. Close to the centre, the deposit is exclusively composed of the new white grains, proving that the flow involves the whole thickness. However, close to the banks, a layer of black grains remained trapped, indicating the presence of a static \cite{Z} layer of thickness $h_{\text{stop}}$ bordered by two levees of thickness larger than $h_{\text{stop}}$ (Fig. 5c) as previously reported \cite{dep}. When $t$ increases, the levee thickness decreases until it vanishes at very long time, so that the deposit corresponding to the asymptotic state is indeed flat. Levees result from the combination between lateral static zones on each border of the flow and the drainage of the central part of the flow after the supply stops \cite{dep}. However, a clear picture is still lacking concerning the junction between a central flat zone of thickness $h_{\text{stop}}$ and a levee of thickness larger than $h_{\text{stop}}$. The flow rule that was obtained here provides a very simple scenario. The flow stops when $R = h_{\text{stop}}$, and one expects the deposit to form by superimposing a layer of thickness $h_{\text{stop}}$ to the static layer. Accordingly the deposit thickness should be $h_{\text{dep}} = Z + h_{\text{stop}}$ wherever $u_s \neq 0$ and $h_{\text{dep}} = Z$ in the quasi-static banks, where $u_s = 0$. Fig 5b) provides the experimental evidence that such a simple scenario indeed holds: the predicted and the measured deposit profiles qualitatively match.

To conclude, by investigating unconfined granular flows down an incline, we have shown that they obey a flow rule which reveals a crossover towards a non local rheology close to the jamming transition. This flow rule accounts for the morphology of the deposit, which actually builds up during the flow, in the form of an underlying static layer. This underlines the importance of addressing erosion-deposition mechanisms issues to complete a full description of geophysical flows.
