A fascinating inverse problem that has been receiving considerable attention is the construction of realizations of random two-phase heterogeneous media with a target two-point correlation function. However, not every hypothetical two-point correlation function corresponds to a realizable two-phase medium. Here we collect all of the known necessary conditions on the two-point correlation functions scattered throughout a diverse literature and derive a new but simple positivity condition. We apply the necessary conditions to test the realizability of certain classes of proposed correlation functions.

1 Introduction

Random two-phase heterogeneous media abound in synthetic products and nature. Examples include composite materials, colloidal dispersions, gels, foams, wood, geologic media, and animal and plant tissue. The effective transport, mechanical and electromagnetic properties of such heterogeneous materials are known to depend on correlation functions that statistically characterize the microstructure. It has recently been suggested that microstructure reconstruction problems can be posed as optimization problems. A set of target correlation functions are prescribed based upon experiments or theoretical models. Starting from some initial realization of the random two-phase medium, the reconstruction
method proceeds to find a realization by evolving the microstructure such that the calculated correlation functions best match the target functions. This intriguing inverse problem is solved by minimizing an error based upon the distance between the target and calculated correlation functions. The two-phase medium can be a dispersion of particles in some matrix (liquid or solid) or, more generally, a digitized image of a two-phase material.

An effective reconstruction procedure enables one to generate accurate structures at will, and subsequent analysis can be performed on the image to obtain desired macroscopic properties (e.g., transport, electromagnetic and mechanical properties) of the media. This becomes especially useful in generating three-dimensional structures from planar information when three-dimensional imaging techniques are not available: a “poor man’s” tomography experiment.

Interestingly, the same procedure has been used to “construct” realizations of two-phase media from a hypothetical target correlation function. In this mode, the procedure is referred to as a construction algorithm. There are many different types of statistical descriptors of two-phase media, but the most basic one is the two-point correlation function, which gives the probability of finding two points in one of the phases (see definition below) and is obtainable from small-angle X-ray scattering. The construction algorithm can be employed to determine if a prescribed two-point correlation function is in fact realizable. If such a two-point correlation function is realizable, then the procedure could be used to categorize classes of random microstructures, which would be a valuable accomplishment. However, not every hypothetical two-point correlation function corresponds to a realizable two-phase medium. Therefore, it is of great fundamental and practical importance to determine the necessary conditions that realizable two-point correlation functions must possess. We note in passing that this question is closely related to realizability issues of pair-correlation functions of many-particle systems.

One aim of this paper is to gather all of the known necessary conditions on the two-point correlation function of two-phase random media, also known as “random closed sets” in the field of stochastic geometry. Some of these conditions are well-known in the physical sciences literature, but others are more arcane and are contained in obscure mathematical technical reports and/or proceedings. We also derive a new but simple positivity condition on the two-point correlation function. We consider some illustrative examples of proposed correlation functions and test whether they can correspond to realizable two-phase random media.
2 Necessary Conditions

Here we collect all of the known necessary conditions on the two-point correlation function of random media that are scattered throughout a diverse literature. We also derive a new positivity condition.

Each realization $\omega$ of the two-phase random medium occupies the region of $d$-dimensional Euclidean space $V \in \mathbb{R}^d$ of volume $V$ that is partitioned into two random sets or phases whose interiors are disjoint: phase 1, a region $V_1(\omega)$ of volume fraction $\phi_1$, and phase 2, a region $V_2(\omega)$ of volume fraction $\phi_2$. For a given realization $\omega$, the indicator function $I^{(i)}(x; \omega)$ for phase $i$ at any position vector $x \in V$ is defined by

$$I^{(i)}(x; \omega) = \begin{cases} 1, & \text{if } x \in V_i(\omega), \\ 0, & \text{otherwise}, \end{cases}$$ (1)

Thus, a two-phase random medium is described by a binary stochastic process $\{I^{(i)}(x) : x \in \mathbb{R}^d\}$. For statistically homogeneous but anisotropic media, the first two correlation functions are given by

$$S^{(i)}_1(x) = \langle I^{(i)}(x) \rangle = \phi_i$$ (2)

and

$$S^{(i)}_2(r) = \langle I^{(i)}(x_1)I^{(i)}(x_2) \rangle,$$ (3)

where $i = 1$ or 2, angular brackets denote an ensemble average, $r = x_1 - x_2$, and the symbol $\omega$ is henceforth dropped for brevity. (The generalization to $n$-point correlation functions for $n \geq 1$ is straightforward.\[3\]) Clearly, $\phi_i$ lies in the closed interval $[0, 1]$ and $\phi_1 + \phi_2 = 1$. The two-point or autocorrelation function $S^{(i)}_2(r)$ for statistically homogeneous media gives the probability of finding the end points of a vector $r$ in phase $i$. Debye and Bueche \[11\] showed that the two-point correlation function of a porous medium can be obtained experimentally via small X-ray scattering. Note that the two-point function for phase 2 is simply related to the corresponding function for phase 1 via the expression

$$S^{(2)}_2(r) = S^{(1)}_2(r) - 2\phi_1 + 1,$$ (4)

and thus the autocovariance function

$$\chi(r) \equiv S^{(1)}_2(r) - \phi_1^2 = S^{(2)}_2(r) - \phi_2^2$$ (5)

for phase 1 is equal to that for phase 2. Generally, for $r = 0$,

$$S^{(i)}_2(0) = \phi_i,$$ (6)
and in the absence of no long-range order,

\[
\lim_{|r| \to \infty} S_2^{(i)}(r) \to \phi_i^2.
\]  

(7)

An important necessary condition for the existence of a two-point correlation function \(S_2^{(i)}(r)\) for a two-phase statistically homogeneous medium \(d\) dimensions is that the \(d\)-dimensional Fourier transform of autocovariance \(\chi(r)\), denoted by \(\tilde{\chi}(k)\), must be nonnegative for all wave vectors, i.e.,

\[
\tilde{\chi}(k) = \int_{\mathbb{R}^d} \chi(r) e^{-i k \cdot r} \, dr \geq 0, \quad \text{for all} \ k,
\]  

(8)

where \(\chi(r)\) is given by (5). Physically, this nonnegativity condition arises because \(\tilde{\chi}(k)\) is proportional to the scattered intensity, which must be positive. This is sometimes called the Wiener–Khintchine condition, which is necessary but not sufficient for the class \(B\) of correlation functions that come from binary stochastic processes \(\{I^{(i)}(x) : x \in \mathbb{R}^d\}\). The Wiener–Khintchine condition is easily proved by exploiting a well-known theorem that states any continuous function \(\chi(r)\) must be positive semi-definite in the sense that for any finite number of spatial locations \(r_1, r_2, \ldots, r_m\) in \(\mathbb{R}^d\) and arbitrary real numbers \(a_1, a_2, \ldots, a_m\),

\[
\sum_{i=1}^{m} \sum_{j=1}^{m} a_i a_j \chi(r_i - r_j) \geq 0
\]  

(9)

if and only if it has a nonnegative Fourier transform \(\tilde{\chi}(k)\). Note that this property does not prevent \(\chi(r)\) from being pointwise negative for certain \(r\). Importantly, whereas the real-space condition is difficult to check, the spectral version (8) is straightforward to test. It is noteworthy that if the medium in \(d\) dimensions is both statistically homogeneous and isotropic, then the one-, two-, \(\cdots\) and \(d\)-dimensional Fourier transforms of \(\chi(r)\) must all be nonnegative. This is a consequence of the fact that \(\chi(r)\) for such a random medium is an invariant in any \(m\)-dimensional subspace, where \(m = 1, 2, \ldots, d - 1\).

The task of determining the necessary and sufficient conditions that \(B\) must possess is very complex. It has been shown that autocovariance functions in \(B\) must not only meet the condition of (8) but another condition on “corner-positive” matrices. Since little is known about corner-positive matrices, this theorem is very difficult to apply in practice. Thus, a meaningful characterization of \(B\) remains an open and interesting problem, especially in the context of \(d\)-dimensional two-phase random media.

No attempt will be made to address the complete characterization of \(B\) here but instead we summarize the known necessary conditions, in addition to condition (8), that characterize \(B\), most of which are described in Ref. (3). The two-point correlation function must satisfy the bounds

\[
0 \leq S_2^{(i)}(r) \leq \phi_i \quad \text{for all} \ r.
\]  

(10)
The lower bound states that $S_2^{(i)}(r)$ must be nonnegative for all $r$, but we show below that either $S_2^{(1)}(r)$ or $S_2^{(2)}(r)$ must strictly be positive for $\phi_i \neq 1/2$. The corresponding bounds on the autocovariance function is given by \[ 3 \]
\[- \min(\phi_1^2, \phi_2^2) \leq \chi(r) \leq \phi_1 \phi_2 \quad \text{for all } r. \]

Another consequence of the binary nature of the process in the case of statistically homogeneous and isotropic media, i.e., when $S_2^{(i)}(r)$ only depends on the distance $r \equiv |r|$, is that its derivative at $r = 0$ is strictly negative or

$$\frac{dS_2^{(i)}}{dr} \bigg|_{r=0} = \frac{d\chi}{dr} \bigg|_{r=0} < 0 \quad \text{for all } 0 < \phi_i < 1. \quad \text{(12)}$$

This is a consequence of the fact that slope at $r = 0$ is proportional to the negative of the specific surface.\[3\] This means that $S_2^{(i)}(r)$ has a cusp at the origin, implying that the two-point function is nonanalytic at the origin. It is a property of binary processes that if $\chi_1(r)$ and $\chi_2(r)$ are in $B$, then $\chi_1(r) \cdot \chi_2(r) \in B$ and $\alpha \chi_1(r) + (1 - \alpha) \chi_2(r) \in B$ for every $\alpha \in [0, 1]$. This was proved by Shepp\[18\] in one dimension, but the proof should extend trivially to $d$ dimensions.

A little known necessary condition for statistically homogeneous media is the so-called “triangular inequality” first derived by Shepp\[18\] and later rediscovered by Matheron:\[19\]

$$S_2^{(i)}(r) \geq S_2^{(i)}(s) + S_2^{(i)}(t) - \phi_i, \quad \text{(13)}$$

where $r = t - s$. The derivation of the triangular inequality \[13\] is straightforward. Following Shepp, we introduce the random variable

$$Y^{(i)}(x) = 2T^{(i)}(x) - 1 = \begin{cases} 1, & \text{if } x \in V_i, \\ -1, & \text{otherwise}, \end{cases} \quad \text{(14)}$$

The mean of $Y^{(i)}(x)$ is $\langle Y^{(i)}(x) \rangle = 2\phi_i - 1$, which is equal to zero if $\phi_1 = \phi_2 = 1/2$. Observe that $Y^{(i)}(x_1) - Y^{(i)}(x_2) + Y^{(i)}(x_3)$ is an odd number (either $-3, -1, 1$ or $3$) and therefore

$$\langle [Y^{(i)}(x_1) - Y^{(i)}(x_2) + Y^{(i)}(x_3)]^2 \rangle \geq 1. \quad \text{(15)}$$

Using the fact that $\langle Y^{(i)}(x_1)Y^{(i)}(x_2) \rangle = 4S_2^{(i)}(x_1 - x_2) - 4\phi_i + 1$, where we have invoked statistical homogeneity, we immediately obtain the triangular inequality \[13\].

Note that if the autocovariance $\chi(r)$ of a statistically homogeneous and isotropic medium is monotonically decreasing, nonnegative and convex (i.e., $d^2 \chi(r)/dr^2 \geq 0$), then it satisfies the triangular inequality \[13\].\[20\] The triangular inequality implies a number of pointwise
conditions on the two-point correlation function. For example, for statistically homogeneous and isotropic media, the triangular inequality implies condition (12), the fact that the steepest descent of the two-point correlation function occurs at the origin, i.e.,

$$|S^{(i)}_2(0)| \geq |S^{(i)}_2(r)|$$ for all $r$, (16)

and the fact that $S^{(i)}_2(r)$ must convex at the origin, i.e.,

$$\left.\frac{d^2 S^{(i)}_2}{dr^2}\right|_{r=0} = \left.\frac{d^2 \chi}{dr^2}\right|_{r=0} \geq 0.$$ (17)

From the “stochastic continuity” theorem for general stochastic processes, it follows that if $S^{(i)}_2(r)$ is continuous at $r = 0$, then it is continuous for all $r$. This continuity condition can also be proved using the triangular inequality. Note that $S^{(i)}_2(r)$ can be discontinuous at the origin if the specific surface $s$ is infinitely large.

The triangular inequality is actually a special case of the more general condition (18)

$$\sum_{i=1}^{m} \sum_{j=1}^{m} \epsilon_i \epsilon_j \chi(r_i - r_j) \geq 1, \quad \epsilon_i \pm 1, \quad i = 1, \ldots, m, \quad m \text{ odd.}$$ (18)

This necessary condition is much stronger than (9), implying that there are other necessary conditions beyond the ones identified so far. However, the condition (18) is difficult to check in practice because it does not have a simple spectral analog in contrast to (9) [cf. (8)]. Note that the integers $\epsilon_i = \pm 1$ in (18) can be replaced with general integers, which would lead to an even more general condition on $\chi(r)$.

Here we report a new simple consequence of the lower bound of expression (11). Because the autocovariance is the same for phase 1 and phase 2, then it immediately follows from the lower bound of (11) that

$$S^{(i)}_2(r) \geq \max(0, 2\phi_i - 1)$$ for all $r$. (19)

Thus, for $\phi_i > 1/2$, $S^{(i)}_2(r)$ is strictly positive such that it must be greater than $2\phi_i - 1$. Interestingly, the lower bound of (11) for the autocovariance $\chi(r)$, first obtained in Ref. 3, was derived from the trivial pointwise nonnegativity condition $S^{(i)}_2(r) \geq 0$. However, the consequences of going back to the two-point correlation function $S^{(i)}_2(r)$ were heretofore not examined. The nontrivial positivity condition (19) arises because the statistics of phase 1 are not independent of the statistics of phase 2. Since $\phi^2_i$ is the large-distance asymptotic limit of $S^{(i)}_2(r)$, its globally minimum value or, more precisely, its infimum (greatest lower bound) must be less than or equal to $\phi^2_i$. (Technically, one must consider the infimum and
not the minimum because the minimum may not actually be achieved, e.g., a monotonically
decreasing function that only asymptotically approaches its minimum value of $\phi_i^2$.) Clearly,
the lower bound \[19\] holds for the infimum of $S_2^{(i)}(r)$, which will be denoted by \[\inf[S_2^{(i)}(r)]\].
In summary, the infimum of any two-point correlation function of a statistically homogeneous
medium must satisfy the inequalities

$$\max(0, 2\phi_i - 1) \leq \inf[S_2^{(i)}(r)] \leq \phi_i^2$$

(20)

(see Figure 1).

Figure 1: Graphs of the upper bound (dashed curve) and lower bound (solid lines) of \[20\] on
the infimum of $S_2^{(i)}(r)$ for a statistically homogeneous medium.

### 3 Illustrative Examples

It is convenient to introduce the scaled autocovariance function $f(r)$ defined as

$$f(r) \equiv \frac{\chi(r)}{\phi_1\phi_2} = \frac{S_2^{(i)}(r) - \phi_i^2}{\phi_1\phi_2} \quad \text{for } 0 \leq r < +\infty.$$  \hspace{1em} (21)

From \[19\], we obtain the triangular inequality for $f$ to be

$$f(r) \geq f(s) + f(t) - 1.$$  \hspace{1em} (22)

Moreover, the bounds \[11\] become

$$-\min\left[\frac{\phi_1}{\phi_2}, \frac{\phi_2}{\phi_1}\right] \leq f(r) \leq 1 \quad \text{for all } r.$$  \hspace{1em} (23)
Our focus in this paper will be hypothetical continuous functions \( f(r) \) that depend on the distance \( r = |\mathbf{r}| \) and could potentially correspond to statistically homogeneous and isotropic media without long-range order such that \( f(0) = 1 \) and \( f(r) \) tends to zero as \( r \to \infty \) sufficiently fast so that the Fourier transform of \( \chi(r) = S_2^{(i)}(r) - \phi_i^2 \) exists. The latter two properties of \( f(r) \) ensure that \( S_2^{(i)}(r) \) obeys its proper asymptotic limiting behaviors as specified by (6) and (7), respectively. When the scaled autocovariance \( f(r) \) depends only on the magnitude \( r = |\mathbf{r}| \), then the Fourier transform condition (8) on \( \tilde{f}(k) \) can be written in any space dimension \( d \) as:

\[
\tilde{f}(k) = (2\pi)^{d/2} \int_0^\infty r^{d-1} f(r) \frac{J_{(d/2)-1}(kr)}{(kr)^{(d/2)-1}} dr \geq 0,
\]

where \( k = |\mathbf{k}| \) and \( J_\nu(x) \) is the Bessel function of order \( \nu \). The bounds (20) are equivalent to

\[
- \min \left\{ \frac{\phi_1}{\phi_2}, \frac{\phi_2}{\phi_1} \right\} \leq f_{\text{inf}} \leq 0,
\]

where \( f_{\text{inf}} \) is the infimum of \( f(r) \). Note that when function \( f(r) \) is independent of the volume fraction \( \phi_1 \), it would correspond, if realizable, to a two-phase medium with phase-inversion symmetry. A two-phase random medium possesses phase-inversion symmetry if the geometry of phase 1 at volume fraction \( \phi_1 \) is statistically identical to that of phase 2 in the system where the volume fraction of phase 1 is \( \phi_2 \) and hence

\[
S_2^{(1)}(\mathbf{r}, \phi_1, \phi_2) = S_2^{(2)}(\mathbf{r}; \phi_2, \phi_1).
\]

By construction, the upper bound of (25) is always satisfied. All of the functions \( f(r) \) considered below are taken to be independent of the volume fraction \( \phi_1 \) and therefore any violation of the lower bound of (25) implies that a two-phase statistically homogeneous and isotropic medium cannot exist for the following volume-fraction intervals

\[
0 < \phi_i < \frac{|f_{\text{inf}}|}{1 + |f_{\text{inf}}|} \quad \text{and} \quad \frac{1}{1 + |f_{\text{inf}}|} < \phi_i < 1.
\]

Figure 2 depicts the bounds (25) on \( f_{\text{inf}} \) for \( f(r) \) that are independent of volume fraction.

First we note that for any \( f(r) \) that monotonically decreases in \( r \) to its long-range value of zero, the pointwise nonnegativity condition (23) is obeyed for \( 0 \leq \phi_i \leq 1 \). However, as some examples below will demonstrate, such an \( f(r) \) does not necessarily obey the triangular inequality (22). A natural example of a monotonic scaled autocovariance function \( f(r) \) is the simple exponentially decaying function, i.e.,

\[
f(r) = \exp(-r/a),\]

(28)
where $a$ is a positive parameter that we call the “correlation length.” This function was first proposed by Debye and coworkers,[11, 23] who intuited that it should correspond to structures in which one phase consists of “random shapes and sizes,” but presented no proof that such was the case. The function (28) obeys the necessary nonnegativity condition (24) on the spectral function $\tilde{f}(k)$ for any $d$ as well as the triangular inequality (22). The satisfaction of these necessary conditions does not ensure that such a correlation is realizable. However, the aforementioned inverse optimization construction technique [7, 3] was applied to generate a two-dimensional digitized realization corresponding to (28) (see Figure 3). This leads one to believe that (28) is exactly realizable. Indeed, there are specific two-phase microstructures that achieve the “Debye” random-medium function (28) in the plane. [16] The function (28) is a special case of a more general realizable subclass of $B$ given by the *completely monotonic functions,* [18] i.e.,

$$f(r) = \int_{0}^{\infty} \exp(-\lambda r) \, dF(\lambda),$$  

(29)

where $F(\lambda)$ is a nonnegative bounded measure [bounded and nonincreasing function on $(0, \infty)$], i.e., $dF \geq 0$ and $\int_{0}^{\infty} dF(\lambda) = 1$. We see that if $F = \Theta(\lambda - a^{-1})$, then $dF = \delta(\lambda - a^{-1})$ and (28) is recovered, where $\Theta(x)$ and $\delta(x)$ are the Heaviside and Dirac delta functions, respectively.

Another natural monotonic scaled autocovariance function $f(r)$ to consider is the Gaussian function, i.e.,

$$f(r) = \exp[-(r/a)^2].$$  

(30)

Although any such Gaussian function has a nonnegative spectral function $\tilde{f}(k)$, it cannot
correspond to a two-phase random medium in $\mathbb{R}^d$ because the slope of $S_2(i)(r)$ at $r = 0$ is zero (i.e., the specific surface is zero) and therefore violates condition (12) or, more generally, the triangular inequality (22). For precisely the same reasons, the class of monotonic functions

$$f(r) = \exp\left[-(r/a)^\alpha\right], \quad \text{for any } \alpha > 1$$

and

$$f(r) = \frac{1}{[1 + (r/a)^2]^{\beta-1}} \quad \text{for any } \beta \geq d$$

cannot correspond to a two-phase random medium in $d$ dimensions. These specific examples, some of which are illustrated in Fig. 4, show that the nonnegativity condition (24) and triangular inequality (13) are independent necessary conditions.

The final monotone function that we test is the simple linear function

$$f(r) = \begin{cases} 
1 - r/a, & \text{if } r \leq a, \\
0, & \text{otherwise,}
\end{cases}$$

Shepp [18] proved that such a scaled autocovariance is realizable by a statistically homogeneous two-phase medium in one dimension. However, this autocovariance is not realizable in higher dimensions because its spectral function $\tilde{f}(k)$ can take on negative values for certain values of $k$. It is noteworthy that it has been shown that for any positive definite $f(r)$ in one dimension, the function $2 \arcsin(f)/\pi$ as well as $8\pi^{-2} \sum_k (2k + 1)^2 f((2k + 1)r)$ are in $B$. [18]

A generalization of the Debye random-medium function (28) that is nonmonotone and would be characterized by short-range order is the following expression: [9]

$$f(r) = e^{-r/a} \frac{\sin(qr)}{qr},$$

Figure 3: Construction of a digitized two-dimensional realization of a “Debye” random medium (400 × 400 pixels). [7, 8] Here the volume fraction $\phi_1 = \phi_2 = 0.5$ and correlation length $a = 2$ pixels.
Figure 4: Examples of scaled autocovariance functions that cannot correspond to statistically homogeneous and isotropic two-phase random media: (1) \( f(r) = 1/(1 + r^2)^4 \) for \( d \leq 5 \); (2) \( f(r) = \exp(-r^2) \) for any \( d \); and (3) \( f(r) = \exp(-r^6) \) for any \( d \).

where \( q \) is an inverse length scale that controls oscillations in the term \( \sin(qr)/(qr) \). The spectral function \( \tilde{f}(k) \) of (34) in one, two, and three dimensions obeys the nonnegativity condition (24). Interestingly, Torquato [3] observed that although (34) satisfies the upper bound of binary condition (11), it does not necessarily satisfy the lower bound of (11) or, equivalently, the lower bound of (23) for all \( \phi_1 \), depending on the values of \( a \) and \( q \). In other words, there are values of the infimum \( f_{\text{inf}} \), which in this case is a true global minimum, that violate the lower bound of (25). Let \( r_0 \) be the radial distance at which \( f(r) \) achieves its global minimum. The minima of \( f(r) \) are solutions to the transcendental equation \( q(a + r) \tan(qr) = q^2 ar \). The extremum value \( qr_0 \) can be shown to lie in the interval \( [\pi, 3\pi/2] \) for arbitrary \( a \) and \( q \). For example, for \( aq = 8\pi \), \( r_0 \approx 5.671a \) and \( f_{\text{min}} \approx -0.1818 \) (see Fig. 5). For example, for \( aq = 8\pi \), \( r_0 \approx 0.1772a \) and \( f_{\text{min}} \approx -0.1818 \) (see Fig. 5), and therefore, according to (27), (34) is not realizable for the volume-fraction intervals

\[
0 < \phi_i < 0.1538 \ldots \quad \text{and} \quad 0.8461 \ldots < \phi_i < 1.
\]

Interestingly, two realizations of digitized two-dimensional two-phase media were previously constructed [3, 8] that putatively correspond to the scaled autocovariance function (34) for \( \phi_2 = 0.2 \) and 0.5, respectively, and the aforementioned choice of \( a \) and \( q \) are shown in Figure 6. At \( \phi_2 = 0.2 \), the system resembles a dilute particle suspension with “particle” diameters of order \( b \). At \( \phi_2 = 0.5 \), the resulting pattern is labyrinthine such that the characteristic sizes of the “patches” and “walls” are of order \( a \) and \( 2\pi/q \), respectively. For these sets of parameters, all of the aforementioned necessary conditions on the function are met, except
Figure 5: The damped sinusoidal function (34) with \( qa = 8\pi \).

for the triangular inequality. Although (34) satisfies the negative slope condition (12) at the origin, it only satisfies the convexity condition (17) for \( qa \leq \sqrt{3} \), which we see is violated in these instances, implying that the triangular inequality must be violated. As it turned out, the construction procedure matched the target function (34) for almost all \( r \), but it could not yield convex behavior in the vicinity of the origin. Since the triangular inequality was not known at the time, it was difficult to ascertain whether the slight discrepancy in the curvature of the function at the origin was numerical imprecision. We now know in retrospect that the construction technique was revealing that a two-phase medium with a scaled autocovariance function (34) cannot be exactly realized, which is a testament to the power of this method.

4 Conclusions

We have identified all of the known necessary conditions on the two-point correlation function \( S_2^{(i)}(r) \) of statistically homogeneous two-phase media and have derived a new but simple positivity condition that it must satisfy. Using these conditions, we were able to ascertain the realizability of certain classes of proposed correlation functions. In future work, it will be important to identify other checkable necessary conditions. The stochastic optimization construction technique [3] appears to be a very powerful numerical tool in guiding such a search. Finally, we note that the analogous realizability problem for the pair correlation function \( g_2 \) of point processes [13, 14, 15, 24, 25] offers many interesting challenges. It has recently been conjectured that the known standard non-negativity conditions on \( g_2 \) are sufficient to ensure the existence of point processes at and above some sufficiently high space dimension [26, 27]. Application of this conjecture implies the possibility that the densest sphere packings in sufficiently
\[ \phi_2 = 0.2 \quad \phi_2 = 0.5 \]

Figure 6: Construction of digitized two-dimensional realizations (400 \( \times \) 400 pixels) that putatively correspond to the target function given by (34) for \( \phi_2 = 0.2 \) and 0.5. Here \( a = 32 \) pixels and \( q = 8\pi/a \). We now know that this function is not exactly realizable because even though the construction technique matched (34) for almost all \( r \), it could not yield the necessary convex behavior in the vicinity of the origin.

High dimensions are disordered rather than periodic, implying the existence of disordered classical ground states for some continuous potentials. In future work, it would be interesting to investigate whether an analogous conjecture applies to binary stochastic processes.
