Condensation of fluctuations is an interesting phenomenon conceptually distinct from condensation on average. One striking feature is that, contrary to what happens on average, condensation of fluctuations may occur even in the absence of interaction. The explanation emerges from the duality between large deviation events in the given system and typical events in a new and appropriately biased system. This surprising phenomenon is investigated in the context of the Gaussian model, chosen as paradigmatical non interacting system, before and after an instantaneous temperature quench. It is shown that the bias induces a mean-field-like effective interaction responsible of the condensation on average. Phase diagrams, covering both the equilibrium and the off-equilibrium regimes, are derived for observables representative of generic behaviors.

I. INTRODUCTION

Condensation is a ubiquitous phenomenon in nature. It may take place in equilibrium, off-equilibrium, in real space or in momentum space. Starting from the most familiar condensation of supersaturated vapour, there is a great abundance of examples which includes, among others, the Bose-Einstein condensation (BEC) \textsuperscript{1} and the related transition in mean-field events, like the spherical \textsuperscript{2} or the large-\(N\) model \textsuperscript{3}. More recently there has been much interest in condensation transitions arising out of equilibrium, both in classical \textsuperscript{4} and quantum systems \textsuperscript{5}. In the non equilibrium context the phenomenology of condensation turns out to be very rich with a variety of manifestations in fields as diverse as economics, information theory, traffic models, granular materials, networks and mass transport \textsuperscript{4,6}. Much progress in the understanding of the basic features common to most of these different instances of condensation has been achieved through the study of driven diffusive systems and, in particular, of the zero-range process or variants of it \textsuperscript{4}.

In this paper we shall focus on a yet another manifestation of condensation, which is somewhat conceptually different. In the usual contexts mentioned above, condensation is a phenomenon observed in the average behavior of the system. Instead, we shall be concerned with condensation occurring in the fluctuations, namely with condensation as a rare event \textsuperscript{7,11}. The conceptual and substantial difference is that condensation of fluctuations may occur even in systems which cannot sustain condensation on average, such as non interacting systems. In order to emphasize this point, we shall work with the Gaussian model, which is the paradigmatical non interacting system in the theory of phase transitions \textsuperscript{12}. Although the average properties of this system are well known to be trivial, in and out of equilibrium, we shall find that fluctuations of extensive quantities may condense.

Most of the work quoted above on condensation, both on average and in the fluctuations, has been carried out in the context of non equilibrium steady states, obtained by driving an externally generated current into the system. Here, instead, we shall carry further the program initiated in Ref. \textsuperscript{9} of exploring fluctuations in the largely unknown area of the processes without time translation invariance \textsuperscript{13}. Specifically, we shall consider the relaxation following the instantaneous quench from an initial temperature \(T_I\) to a lower temperature \(T_F\). With such a choice, we can overview the entire evolution from the equilibrium behavior before the quench to the off equilibrium relaxation after the quench. We shall see that, depending on the nature of the observable, fluctuations may condense either in and out of equilibrium, or just as an out of equilibrium phenomenon. We shall analyse in detail the mechanism of condensation and we shall derive phase diagrams, extending into the time direction. These diagrams show that during relaxation condensation is enhanced by the dynamics, if occurring also in equilibrium, or dynamically generated if absent in equilibrium.

The paper is organized as follows: In section \textsuperscript{II} we set up the ensemble theory apparatus needed in the rest of the paper. The Gaussian model is introduced in section \textsuperscript{III} Section \textsuperscript{IV} is the central section of the paper, where the notions of condensation on average and condensation of the fluctuations are discussed in general. The example of a macrovariable condensing both in equilibrium and off equilibrium is treated in section \textsuperscript{V} while the example of condensation as an out-of-equilibrium phenomenon is discussed in section \textsuperscript{VI}. Concluding remarks are made in section \textsuperscript{VII}.

II. ENSEMBLES

The apparently puzzling feature of condensation appearing in the fluctuations of a non interacting system finds explanation in the framework of large deviation theory \textsuperscript{14}, through the mapping of rare fluctuations in
the given system (in our case the Gaussian model) into
typical events in a new system, obtained by the applica-
tion of an appropriate bias. The key point, as we shall
see, is that the bias produces an effective interaction,
which is responsible of the condensation on average in the
biased system. The basic idea amounts to an exten-
sion of ensemble theory beyond the realm of equilibrium
statistical mechanics, according to a scheme which has
been recently used in a variety of different contexts,
classical\textsuperscript{15}\textsuperscript{17} and quantum\textsuperscript{18}.

In order to give a general presentation of the
method, let us consider a generic probability distribu-
tion $P(\varphi, J)$, referred to as the prior and describing
the state of a system of volume $V$, with microstates consisting
of sets of degrees of freedom $\varphi = [\varphi_i]$, where $i$ is a
generic label, and control parameters $J$. In this paper $i$
is the position vector $\vec{x}$ in real space or the wave vector
$\vec{k}$ in Fourier space, and $J$ stands for temperature $T$ in
equilibrium or for time $t$ off equilibrium. The probabil-
ity of a fluctuation $M$ of a random variable $\mathcal{M}(\varphi)$ is
given by

$$P(M, J) = \int_\Omega d\varphi P(\varphi, J)\delta(M - \mathcal{M}(\varphi)) \quad (1)$$

where $\Omega$ is the phase space. Introducing the integral
representation of the $\delta$ function $\delta(x) = \int_0^{\alpha+i\infty} \frac{dz}{2\pi i} e^{-zx}$
this becomes

$$P(M, J) = \int_{\alpha-i\infty}^{\alpha+i\infty} \frac{dz}{2\pi i} e^{-z^2 M} K_M(z, J) \quad (2)$$

where

$$K_M(z, J) = \langle e^{z\mathcal{M}(\varphi)} \rangle \quad (3)$$

is the moment generating function of $\mathcal{M}$ and the brack-
ets $\langle \cdot \rangle$ denote the average in the prior ensemble. If the
system is extended and $\mathcal{M}(\varphi)$ is an extensive macrovari-
able, for large volume Eq. (2) can be rewritten as

$$P(M, J, V) = \int_{\alpha-i\infty}^{\alpha+i\infty} \frac{dz}{2\pi i} e^{-V[z^2 + \lambda_M(z, J)]} \quad (4)$$

where $m$ is the density $M/V$ and

$$-\lambda_M(z, J) = \frac{1}{V} \ln K_M(z, J, V) \quad (5)$$

is the volume independent scaled cumulant generating function. Carrying out the integration by the saddle
point method, the large deviation principle is obtained

$$P(M, J, V) \sim e^{-V I_M(m, J)} \quad (6)$$

with the rate function

$$I_M(m, J) = z^* m + \lambda_M(z^*, J) \quad (7)$$

and where $z^*(m, J)$ is the solution, supposedly unique,
of the saddle point equation

$$\frac{\partial}{\partial z} \lambda_M(z, J) = -m. \quad (8)$$

From the above algebra follows the basic result of
large deviation theory\textsuperscript{14} that $I_M(m, J)$ and $\lambda_M(z, J)$
form a pair of Legendre transforms. Therefore, regarding
the latter quantity as the “free energy” of the new ensemble

$$P(\varphi, z, J, V) = \frac{1}{K_M(z, J, V)} P(\varphi, J, V) e^{z \mathcal{M}(\varphi)} \quad (9)$$

obtained by imposing the exponential bias on the prior, the
rate function remains identified with the “thermo-
dynamic potential” associated to yet another ensemble

$$P(\varphi, M, J, V) = \frac{1}{P(M, J, V)} P(\varphi, J, V) \delta(M - \mathcal{M}(\varphi)) \quad (10)$$

in which the bias is implemented rigidly through the
phase space restriction $M = \mathcal{M}(\varphi)$. To make contact
with familiar ground, if the prior was the uniform en-
semble $P(\varphi, V) = 1/|\Omega(V)|$ and $\mathcal{M}$ the energy of the
system, then $P(\varphi, z, V)$ and $P(\varphi, M, V)$ would be,
respectively, the usual canonical ensemble at the inverse
temperature $\beta = -z$ and the microcanonical ensemble
with energy $E = M$.

We stress that the above chain of relations holds in
general, without limitations to equilibrium. Therefore,
the quantity $I_M(m, J)$ plays two distinct roles\textsuperscript{8} \textsuperscript{11}
\textsuperscript{16}: on the one hand it acts as the rate function regu-
lating the occurrence of rare events in the prior en-
semble and on the other hand it is the thermodynamic
potential accounting for the average properties in the
constrained ensemble $P(\varphi, M, J, V)$. In particular, if the
extra correlations due to the bias are responsible of singularities in the free energy, amenable to a phase transition,
the same singularities arise in the unbiased fluctuations. Consequently, the same phenomenon, in
principle, could be observed following different exper-
imental protocols, either by leaving the system unbi-
ased and monitoring fluctuations or, alternatively, by
arranging the appropriate bias aimed to render typical
the effect of interest.

III. THE GAUSSIAN MODEL

In order to produce a concrete and simple realiza-
tion of the above ideas, let us consider the Gaussian
model, which describes a system of volume $V$, with a
scalar order parameter field $\varphi(\vec{x})$ and the bilinear en-
ergy functional

$$\mathcal{H}[\varphi] = \frac{1}{2} \int_V d\vec{x} [\nabla \varphi]^2 + r \varphi^2(\vec{x}) \quad (11)$$

where $r$ is a non negative mass. The system is prepared
in equilibrium at the temperature $T_1$. At the time $t = 0$
is instantaneously quenched to the lower temperature
$T_F$. The dynamics, without conservation of the order
parameter, are governed by the overdamped Langevin
equation\textsuperscript{12} \textsuperscript{19}

$$\dot{\varphi}(\vec{x}, t) = [\nabla^2 - r] \varphi(\vec{x}, t) + \eta(\vec{x}, t) \quad (12)$$
where $\eta(\vec{x}, t)$ is the white Gaussian noise generated by the cold reservoir, with zero average and correlator

$$
(\eta(\vec{x}, t)\eta(\vec{x}', t')) = 2T_F \delta(\vec{x} - \vec{x}') \delta(t - t').
$$

Due to linearity, the problem can be diagonalized by Fourier transformation. Keeping in mind that the Fourier components $\varphi_{\vec{k}} = \int \! d\vec{x} \varphi(\vec{x}) e^{i\vec{k} \cdot \vec{x}}$ are complex, some care is needed in the identification of the independent variables. Let us denote by $\mathcal{B}$ the set of all wave vectors with magnitude smaller than an ultraviolet cutoff $\Lambda$, caused by the existence of a microscopic length scale in the problem, like an underlying lattice spacing. Since the reality of $\varphi(\vec{x})$ requires $\varphi_{-\vec{k}} = \varphi_{\vec{k}}^\ast$, the independent variables are $\varphi_0$ and the set of pairs $\{u_{\vec{k}} = \Re \varphi_{\vec{k}}, \ v_{\vec{k}} = \Im \varphi_{\vec{k}}\}$ with $\vec{k} \in \mathcal{B}_+$, where $\mathcal{B}_+$ is a half of $\mathcal{B}$. More precisely, if $\mathcal{B}_-$ is the set obtained by reversing all the wave vectors in $\mathcal{B}_+$, then $\mathcal{B}_+$ is such that $\mathcal{B}_+ \cap \mathcal{B}_- = \emptyset$ and $\mathcal{B}_+ \cup \mathcal{B}_- = \mathcal{B} - \{0\}$. However, rather than working with $\mathcal{B}_+$, it is more convenient to let $\vec{k}$ to vary over the whole of $\mathcal{B}$ by taking as independent real variables

$$
\vec{x}_{\vec{k}} = \begin{cases} 
\varphi_0, & \text{for } \vec{k} = 0, \\
u_{\vec{k}}, & \text{for } \vec{k} \in \mathcal{B}_+, \\
v_{\vec{k}}, & \text{for } \vec{k} \in \mathcal{B}_-. 
\end{cases}
$$

With this convention, from Eq. (12) we get the equations of motion for a set of independent Brownian oscillators

$$
\dot{x}_{\vec{k}}(t) = -\omega_k x_{\vec{k}}(t) + \zeta_{\vec{k}}(t)
$$

with the dispersion relation $\omega_k = (k^2 + r)$. The noise correlator is given by

$$
(\zeta_{\vec{k}}(t)\zeta_{\vec{k}}(t')) = 2T_F k V \delta_{\vec{k}, -\vec{k}} \delta(t - t')
$$

where

$$
T_{F,k} = \frac{T_F}{2\theta_k}
$$

and $\theta_k$ is the Heaviside step function with $\theta_0 = 1/2$. The energy functional (11) then takes the separable form

$$
\mathcal{H}(\mathbf{x}) = \sum_{\vec{k}} \mathcal{H}_{\vec{k}}(x_{\vec{k}})
$$

with

$$
\mathcal{H}_{\vec{k}}(x_{\vec{k}}) = \frac{1}{V} \theta_k \omega_k x_{\vec{k}}^2
$$

and where $\mathbf{x}$ stands for the whole set $\{x_{\vec{k}}\}$.

Due to mode independence, the state of the system is factorized at all times $P(\mathbf{x}, t) = \prod_{\vec{k}} P_{\vec{k}}(x_{\vec{k}}, t)$, with the single-mode contributions given by

$$
P_{\vec{k}}(x_{\vec{k}}, t) = Z_{\vec{k}}^{-1}(t)e^{-\beta_k(t)\mathcal{H}_{\vec{k}}(x_{\vec{k}})}
$$

IV. FLUCTUATIONS OF A MACROVARIABLE

Let us now consider a quadratic and separable macrovariable $\mathcal{M}(\mathbf{x}) = \sum_{\vec{k}} \mathcal{M}_{\vec{k}}(x_{\vec{k}})$, with $\mathcal{M}_{\vec{k}}(x_{\vec{k}}) =\ldots$
the saddle point equation (27) can be rewritten as

\[ m = F_M(z, t) \]  

as a typical phenomenon or as a rare fluctuation. The limit is given by the prior expectations. This turns out to be positive, \( \rho_k \), to be specified. According to the scheme of section II, all the information on an underlying interacting theory, whose free information is the average per mode in the biased ensemble (9). Recalling the definition (26) of \( \rho_k \), the above equation can be rewritten as

\[ \langle M_k \rangle_z = \frac{1}{2} \frac{1}{\langle M_k(t) \rangle^{-1} - 2z} \]  

in which the biased and the prior averages enter in the same formal relationship as the dressed and the bare average in a Dyson-Schwinger-type equation [21, 22], with 2z playing the role of the tadpole self-energy. Now, since truncating the self-energy skeleton expansion to the tadpole contribution amounts to a self-consistent mean-field approximation, as in the large \( N \) limit of an \( O(N) \) model 22 23, we have that biased expectations can be viewed as arising from the mean-field approximation on an underlying interacting theory, whose free limit is given by the prior expectations. This turns out to be essential for the distinction between condensation as a typical phenomenon or as a rare fluctuation.

Transforming the sum in Eq. (28) into an integral, the saddle point equation (27) can be rewritten as

\[ m = F_M(z, t) \]  

and

\[ \langle M_k \rangle_z = \frac{1}{2} \frac{1}{\langle M_k(t) \rangle^{-1} - 2z} \]  

in which the biased and the prior averages enter in the same formal relationship as the dressed and the bare average in a Dyson-Schwinger-type equation [21, 22], with 2z playing the role of the tadpole self-energy. Now, since truncating the self-energy skeleton expansion to the tadpole contribution amounts to a self-consistent mean-field approximation, as in the large \( N \) limit of an \( O(N) \) model 22 23, we have that biased expectations can be viewed as arising from the mean-field approximation on an underlying interacting theory, whose free limit is given by the prior expectations. This turns out to be essential for the distinction between condensation as a typical phenomenon or as a rare fluctuation.

Inserting this result into Eq. (5), the saddle point equation (8) can be written as

\[ m = F_M(z, t) \]  

and

\[ \langle M_k \rangle_z = \frac{1}{2} \frac{1}{\langle M_k(t) \rangle^{-1} - 2z} \]  

in which the biased and the prior averages enter in the same formal relationship as the dressed and the bare average in a Dyson-Schwinger-type equation [21, 22], with 2z playing the role of the tadpole self-energy. Now, since truncating the self-energy skeleton expansion to the tadpole contribution amounts to a self-consistent mean-field approximation, as in the large \( N \) limit of an \( O(N) \) model 22 23, we have that biased expectations can be viewed as arising from the mean-field approximation on an underlying interacting theory, whose free limit is given by the prior expectations. This turns out to be essential for the distinction between condensation as a typical phenomenon or as a rare fluctuation.

In this paper, for simplicity, we shall limit the discussion to cases with \( k_M = 0 \). Then, if \( [\rho_k(t) - \rho_0(t)] \) vanishes with \( k \) like \( k^\alpha \), for \( d \leq \alpha \) the singularity is not integrable, \( m_C(t) \) diverges and the solution (33) exists for any \( m \geq 0 \). This is shown in the top panel of Fig. 2.
Instead, if \( d > \alpha \), the singularity is integrable, \( m_{\text{C}}(t) \) is finite and the solution [63] exists only for \( m \leq m_{\text{C}}(t) \) (bottom panel of Fig. 2). In order to find the solution for \( m > m_{\text{C}}(t) \) one must proceed as in the standard treatment of BEC [1], separating the \( k = 0 \) term from the sum and rewriting Eq. (34) as

\[
m = \frac{1}{V} \langle M_0 \rangle_{z^*} + F_M(z^*, t). \tag{36}
\]

Then, \( m_{\text{C}}(t) \) defines a critical line on the \((t, m)\) plane separating the normal phase (below) from the condensed phase (above). Below the first term in the right hand side of Eq. (36) is \( \mathcal{O}(1/V) \) and negligible, while above (see Fig. 2) takes the finite value \( [m - m_{\text{C}}(t)] \), due to the “sticking” [1, 2] of \( z^* \) to the \( m \)-independent value \( z^* = \rho_0(t) \). Summarising,

\[
z^*(m, t) = \begin{cases} F_M^{-1}(m, t), & \text{for } m \leq m_{\text{C}}(t), \\ \rho_0(t), & \text{for } m > m_{\text{C}}(t), \end{cases} \tag{37}
\]
as it is illustrated in the bottom panel of Fig. 2. What we have derived, so far, is condensation on average in the framework of the biased ensemble. That is, the transition from microscopic to macroscopic of the expectation \( \langle M_0 \rangle_{z^*} \), analogous to BEC for the zero momentum occupation number. We emphasize, for future reference, that the occurrence of the transition requires i) that the intensive parameter \( \rho \) conjugate to \( \mathcal{M} \) does depend on \( k \), i.e. that there exists a spectrum of parameters \( \rho_k \) and ii) that the spectrum vanishes with \( k \) as \( k^\alpha \) with \( \alpha < d \).

\[
\begin{align*}
\text{FIG. 3: Rate function } I_\mathcal{E}(s, t) \text{ for the sample variance discussed in section } &\text{X. SC denotes the critical threshold. Parameters } \mu_k = 2, t = 2, r = 1, T_I = 1, T_F = 0.2, d = 3. \\
\end{align*}
\]

In order to see the dual image of this transition in the fluctuations occurring in the prior ensemble [24], we must take a look at the rate function. Taking into account the definition (7) and the above result for \( z^*(m, t) \), we have

\[
I_\mathcal{M}(m, t) = \begin{cases} z^*(m, t)m + \lambda_M(z^*(m, t), t), & \text{for } m \leq m_{\text{C}}(t) \\ \rho_0(t)(m - m_{\text{C}}) + I_\mathcal{M}(m_{\text{C}}, t), & \text{for } m > m_{\text{C}}(t) \end{cases} \tag{38}
\]

whose typical behavior is displayed in Fig. 3 obtained for the sample variance discussed below in section VI. Thus, the probability of a fluctuation with \( m > m_{\text{C}}(t) \) is given by

\[
P(M, t) \sim e^{-V\rho_0(t)(m - m_{\text{C}})}e^{-V I_\mathcal{M}(m_{\text{C}}, t)}. \tag{39}
\]

On the other hand, the fluctuations probability can also be written as

\[
P(M, t) = \int \prod \delta(M - \sum \mathcal{M}_k) \tag{40}
\]

where \( \mathcal{M}_k \) is a configuration of the values taken by the single-mode observables \( \mathcal{M}_k \). The statement is simply that, once \( M \) has been fixed, the allowed microscopic events \( \mathcal{M}_k \) are those on the hypersurface defined by the constraint \( M = \sum \mathcal{M}_k \) and that the probability \( P(M, t) \) is obtained by summing over the shell. The probability of one such configuration is given by

\[
P(\mathcal{M}_k, t) = \prod \mathcal{P}_k(\mathcal{M}_k, t) \tag{41}
\]

where \( \mathcal{P}_k(\mathcal{M}_k, t) \), appearing in the right hand side, using Eqs. (2) and (25), is given by

\[
\mathcal{P}_k(\mathcal{M}_k, t) = \frac{e^{-\rho_k^{-1} M_k}}{\sqrt{\pi \rho_k^{-1} M_k}} \tag{42}
\]

and \( \theta \) is, again, the Heaviside step function. Now, inserting this result into Eq. (40) and comparing with Eq. (39), we obtain

\[
P(M, t) = \int dM_0 P_0(M_0, t)\delta(M_0 - (M - M_{\text{C}})) \times \int \prod \mathcal{P}_k(\mathcal{M}_k, t)\delta(M_{\text{C}} - \sum \mathcal{M}_k) \tag{43}
\]

which means that, for \( m > m_{\text{C}}(t) \), the probability of the configurations \( \{\mathcal{M}_k\} \) is concentrated on the subset of the shell singled out by the additional condition \( M_0 = M - M_{\text{C}} \). This is condensation of fluctuations, in the sense that a fluctuation above the threshold \( M_{\text{C}} \) occurs only if the macroscopic fraction \( M - M_{\text{C}} \) of it is contributed by the zero mode. As anticipated in section [4] the remarkable feature of this transition is that it takes place in a non interacting system, like the Gaussian model, in which no transition on average can take place, in and out of equilibrium. The explanation is in Eq. (40), which shows how the bias generates the interaction sustaining the transition, and the bias is generated once the size of the fluctuation has been fixed.

As an illustration, in the next sections we shall analyze two specific cases. In the first one condensation occurs both in equilibrium and out of equilibrium, while in the second one it occurs exclusively as an out of equilibrium phenomenon.
V. ORDER PARAMETER SAMPLE VARIANCE

Let us consider the sample variance

\[ S[\varphi] = \int_V d\bar{x} \varphi^2(\bar{x}) = \frac{1}{V} \sum_k \theta_k x_k^2 \]  

(43)

as the fluctuating macrovariable. This corresponds to \( \mu_k = 2 \), which is independent of \( k \) and yields \( \rho_k(t) = \beta_k \omega_k/2 \). From the small \( k \) behavior \( |\rho_k(t) - \rho_0(t)| \sim k^2 \) follows \( \alpha = 2 \) for all times, including the initial and the final equilibrium states (bottom panel of Fig. 1). Therefore, denoting by \( s \) the density \( S/V \), the critical value \( s_c(T) \) is finite for \( d > 2 \) at all times. The critical line for \( d = 3 \) is displayed in the top panel of Fig. 4. In order to understand this phase diagram, one should keep in mind that fixing the value of \( s \) amounts to implement a spherical constraint à la Berlin and Kac [2]. Let us first consider equilibrium, in the time region \( t \leq 0 \) preceding the quench. Here, the critical line is horizontal and corresponds to the critical threshold \( s_c(T_f) \) of the spherical model in the temperature \( T_f \) [24]. Then, according to the dual point of view expounded above, the two alternative readings of the equilibrium transition are that condensation can be observed either as the usual transition of the spherical model or as a rare event in the Gaussian model, where the sample variance is free to fluctuate.

Consider, next, the relaxation regime after the quench, for \( t > 0 \). As it is evident from Fig. 4 there are two time regimes separated by the minimum of the critical line, about the characteristic time \( \tau \sim r^{-1} \), which is the relaxation time of the slowest mode. In the first regime \( (0 < t < \tau) \) the system is strongly off equilibrium and the threshold \( s_c(t) \) drops abruptly. In the second regime \( (t > \tau) \) the system gradually equilibrates to the final temperature and \( s_c(t) \) saturates slowly toward the final equilibrium value \( s_c(T_f) < s_c(T_0) \). A few observations are in order: i) The plot of the unbiased average \( \langle s(t) \rangle \) lies below the critical line, showing that condensation of fluctuations is always a rare event. However, the plot of \( [s_c(t) - \langle s(t) \rangle] \) shows that the rarity of the condensation event varies with time and that the most favourable time window for condensation is around \( \tau \), where the difference is minimized. Hence, condensation of the fluctuations is enhanced by the off equilibrium dynamics. ii) The nonmonotonicity of the critical line is a remarkable dynamical feature, leading to a re-entrance phenomenon. Namely, when the transition is driven by \( t \), and \( s \) is kept fixed to a value in between \( s_c(T_f) \) and \( s_c(T_0) \), a fluctuation of this size at first is normal and then condenses, while for \( s \) in between the minimum of the critical line and \( s_c(T_f) \), the fluctuation undergoes a second and reverse transition becoming normal again at late times. iii) The dynamical condensation here analysed is not related to the properties of the dynamical spherical model [27], which requires the spherical constraint to be imposed pathwise, namely at all times after the quench. Here, instead, the evolution is unconstrained and the spherical constraint is imposed only at the observation time \( t \). Therefore, while in equilibrium the two experimental protocols, fluctuations monitoring vs bias implementation, are in principle both realizable, the latter one requiring an instantaneous bias is hardly realizable off equilibrium.

![FIG. 4: Top panel: Phase diagram of order parameter sample variance. The upper horizontal dashed line corresponds to \( s_c(T_f) \). The green line is the plot of \( \langle s(t) \rangle \). The lower dashed line is the difference \( [s_c(t) - \langle s(t) \rangle] \). Bottom panel: Energy phase diagram. In both cases: \( r = 1, T_i = 1, T_F = 0.2, d = 3 \).](image)

VI. ENERGY

As a second example, let us consider the energy [13] as the fluctuating macrovariable. This is representative of a different class of observables, whose fluctuations behave normally in equilibrium and undergo a condensation transition as an out of equilibrium phenomenon. This is due to \( \mu_k = \omega_k \), from which follows \( \rho_k = \beta_k \). Therefore, the \( k \) dependence of \( \rho_k \) disappears in equilibrium (Fig. 1) shifting to infinity the critical threshold. More in detail, denoting by \( e \) the energy density, the critical line is given by

\[ e_c(t) = \int_0^\Lambda \frac{dk}{4\pi^2} \frac{k^2}{\beta_k(t) - \beta_0(t)}. \]  

(44)

The corresponding phase diagram, in the bottom panel of Fig. 4 is qualitatively different from the one in the
top panel for the absence of the phase transition in equilibrium. This is due to the fact that, in equilibrium, the denominator \((\beta k - \beta_0)\) under the integral vanishes identically for all \(k\). This implies \(\alpha \to \infty\) and the divergence of both \(e_C(T_f)\) and of \(e_C(T_F)\) for any space dimensionality \(d\). However, as soon as the system is put off equilibrium, equipartition is broken and the spectrum of inverse effective temperatures develops a minimum at \(k = 0\) (Fig. 1). Then, the integral becomes convergent for \(d > 2\). Consequently, \(e_C(t)\) drops down from infinity to a minimum around \(\tau\) and, then, rises again toward infinity as the system reaches the final equilibrium state. The nonmonotonic shape of the critical line implies, also in this case, re-entrance of the \(t\)-driven transition for all fluctuations above the minimum of the critical line.

VII. CONCLUSIONS

In summary, we have analysed the behavior of fluctuations of macrovariables in the Gaussian model, both in equilibrium and in the off equilibrium relaxation following a sudden temperature quench. For a certain class of bilinear variables, there is condensation in the behavior of large deviations, in the sense that the \(k = 0\) mode contributes a macroscopic amount to the fluctuations. The transition in the fluctuations is dual to an ordinary transition, sustained by an effective mean-field interaction, in the constrained or biased system. Differently from previous work on condensation, we have considered equilibrium followed by relaxation through a non stationary process, in which the time evolution plays an essential role. Also, essential is the \(k\)-space structure of macrovariables and the dispersion relation in the prior model, which is a feature not present in models with identically distributed variables [11]. In this respect, it is particularly interesting the case of energy fluctuations as an instance in which the \(k\) dependence of the conjugate intensive parameters \(\rho\) is dynamically generated and, with it, also the occurrence of condensation. Finally, duality is a general property, not limited to the case of a non interacting prior. Future work will be devoted to the investigation of fluctuations singularities in the case of interacting systems.

[24] This type of transition was first observed in the fluctuations of the heat exchanged by a ferromagnet quenched below the critical point in Ref. [9] and in the fluctuations of composite operators whose average are correlations and response functions in Ref. [11].
[25] In the usual treatment of the spherical model [2], one fixes \(s = 1\) and the transition is driven by \(T\). Conversely, here \(T_f\) is fixed and the transition is driven by \(s\).
