As emerging tick born rickettsial diseases caused by *A. phagocytophilum* and *E. chaffeensis*, anaplasmosis and ehrlichiosis have become a serious threat to human and animal health throughout the world. In particular, in China, an unusual transmission of nosocomial cases of human granulocytic anaplasmosis occurred in Anhui Province in 2006 and more recent coinfection case of *A. phagocytophilum* and *E. chaffeensis* was documented in Shandong Province. Although the seroprevalence of human granulocytic anaplasmosis (former human granulocytic ehrlichiosis, HGE) has been documented in several studies, these data existed on local investigations, and also little data was reported on the seroprevalence of human monocytic ehrlichiosis (HME) in China. In this cross-sectional epidemiological study, indirect immunofluorescence antibody assay (IFA) proposed by WHO was used to detect *A. phagocytophilum* and *E. chaffeensis* IgG antibodies for 7,322 serum samples from agrarian residents from 9 provinces/cities and 819 urban residents from 2 provinces. Our data showed that farmers were at substantially increased risk of exposure. However, even among urban residents, risk was considerable. Seroprevalence of HGA and HME occurred in diverse regions of the country and tended to be the highest in young adults. Many species of ticks were confirmed carrying *A. phagocytophilum* organisms in China while several kinds of domestic animals including dog, goats, sheep, cattle, horse, wild rabbit, and some small wild rodents were proposed to be the reservoir hosts of *A. phagocytophilum*. The broad distribution of vector and hosts of the *A. phagocytophilum* and *E. chaffeensis*, especially the relationship between the generalized susceptibility of vectors and reservoirs and the severity of the disease’s clinical manifestations and the genetic variation of Chinese HGA isolates in China, is urgently needed to be further investigated.
1. Introduction

Anaplasmosis and ehrlichiosis are emerging tick-borne rickettsial diseases (TBRDs) caused by the obligate intracellular bacteria *Anaplasma phagocytophilum* and *Ehrlichia chaffeensis*, respectively [1–3]. These two rickettsiae are both in the family Anaplastaceae, but are different genera. Both bacteria are transmitted by hard ticks, and certain wild rodents and animals are reservoirs. In China, *A. phagocytophilum* bacteria had been isolated from *Apodemus agrarius*, *Tscherksia triton*, and sheep, respectively, and these animals might be reservoir hosts of *A. phagocytophilum* [4]. Moreover, a recent national investigation assessing the epidemiological status of *A. phagocytophilum* among domestic animals in 10 provinces/cities in China showed that some domestic animals including dogs, goats, and cattle might be important reservoir hosts of *A. phagocytophilum* [5].

Although the diagnosis of anaplasmosis and ehrlichiosis is difficult, the annual numbers of infections reported throughout the world have steadily increased [6, 7] since the first recognition of *E. chaffeensis* in 1986 [8] and of *A. phagocytophilum* in 1990 [9]. Seroepidemiological data from the United States suggest that infection rates of *A. phagocytophilum* in endemic areas are as high as 15–36% [10, 11]. In China, an investigation in Tianjin City, one of the largest municipalities and the largest trade port in the northern part of China, revealed that the average seroprevalence in farmers was 8.8% in 2006 [12]. In the United States, the incidence rate of *E. chaffeensis* increases from 0.8 to 3.0 cases/10^5/year during 2000–2007, the hospitalization rate is 49.0%, and the case-fatality rate is 1.9% [7]. A recent investigation assessing the seroepidemiological status of *E. chaffeensis* among rural residents in Beijing indicated that the seroprevalence was 16.4% [13].

However, both anaplasmosis and ehrlichiosis are often underrecognized in China because epidemiological, ecological, clinical, and microbiological information about these two bacteria is very limited, and both diseases are often misdiagnosed due to their clinical manifestation’s similarity to hemorrhagic fever with renal syndrome (HFRS) [14–16]. A typical example of misdiagnosis is the unusual cluster of nosocomial transmission of human granulocytic anaplasmosis (HGA) in a hospital in Anhui province in 2006. The index patient was originally misdiagnosed with HFRS, and five relatives of the patient and four medical workers were secondarily infected with HGA due to contact with blood or respiratory secretions, while the index patient experienced extensive hemorrhage and underwent endotracheal intubation [17].

Despite serological, molecular, and even etiological evidence demonstrating the nationwide distribution of *A. phagocytophilum* infections in humans, domestic animals, ticks, and rodents [4, 12–19], large-scale laboratory-based serological investigations among rural residents who may be at an increased risk of occupational and residential exposure are limited. Thus, it is crucial to obtain epidemiological data on geographical, occupational, and residential risk factors that could increase disease exposure. Herein, a cross-sectional epidemiological study of people residing in rural and urban areas was undertaken during March–May, 2009.

2. Materials and Methods

2.1. Ethics Statement. The study and the collection protocol were approved by the China CDC Institutional Review Board (no. 201103). Written consent was obtained before the blood sampling of participants. Parents provided written informed consent on behalf of all child participants. Preparations of positive rabbit sera used for quality control of antigen slide in the study were produced by rabbit immunization, and all experimental procedures were conducted to conform to the National Institutes of Health Guide for Care and Use of Laboratory Animals (J. Derrell Clerk, Ed., National Academy Press, Washington, DC, USA, 1996.) The Animal Ethics Committee of the Chinese Center for Diseases Control and Prevention approved a document on the experimental procedures (201104).

2.2. Study Area and Time. The nine provinces Zhejiang, Anhui, Jiangsu, Henan, Yunnan, Hainan, Xinjiang, Jilin, and Heilongjiang and the two independent municipalities Beijing and Tianjin were chosen based on the availability of information on recorded rickettsial infections for each province/city from March to May, 2009. The investigation time and order for each province/city were determined based on the breeding peak of ticks in the local areas. For each province or city, three or five rural counties were selected based on geographic location, for example, the eastern, southern, western, northern, and central areas of each province, to identify the investigation sites. In the same way, three to five villages were chosen based on their geographic locations in each county.

2.3. Study Population. Considering the age distribution and the accordance of labor style, the family as unit was investigated and sampled. Local permanent residents were selected from among the local government-registered families; for example, families were selected based on the last digit (odd or even) of the registration number of their registered permanent residence. For each selected family, every individual, including spouses and children, was included in the study. A standard questionnaire was used according to the “Guideline for the Control and Prevention of Human Granulocytic Anaplasmosis” issued by the Ministry of Public Health of the People’s Republic of China in 2008 (the Ministry of Public Health of the People’s Republic of China, 2008, No. 18). The demographic data collected included general information, such as sex, age, place of residence (plain areas or hilly regions), occupation (planting crops, planting fruit trees, or the unemployed, including retired people, students, and preschool children), the length of working time per day, the length of service time, and past medical history. The participants had to answer whether they could recognize ticks, whether they had been bitten by ticks, and how frequently they had been bitten by ticks within the last year.
All participants were asked whether they had a fever on the day of the survey and whether they had had a fever (temperature of ≥38.0°C) during the preceding 12 months. If so, they were asked about clinical manifestations, such as myalgia or headache.

In addition to the rural residents mentioned above, a total of 819 samples from urban residents, including 566 sera from Daqing city, Heilongjiang province, and 253 sera from Yanbian city, Jilin province, were collected during 2007-2008 and included in the study. The demographic data were recorded in the same way as for the rural residents.

2.4. Sampling and Laboratory Detection. A 2 mL sample of nonanticoagulated blood was collected from each participant after written informed consent was obtained. Samples were temporarily stored in a cooler and then transferred to the local county CDC for serum separation. The blood samples were centrifuged at 1,500 rpm for 10 min, and the separated sera were stored at −20 or −40°C at the local CDC and then transferred to the Department of Rickettsiologia, National Institute for Communicable Disease Control and Prevention, China CDC, by air within 48 or 72 hours and stored at −80°C until laboratory testing.

Immunofluorescence assays (IFA) were performed for IgG antibody detection according to the reference methods proposed [20]. To reduce laboratory errors, testing of all samples was performed within a limited time frame (from May to August 2009). *E. chaffeensis* (Arkansas strain) antigen was provided by Dr. Robert Massung at the United States CDC. The *A. phagocytophilum* strain Webster was kindly provided by J. S. Dumler at the Johns Hopkins University School of Medicine. These two antigens were spotted in different rows in the same slide to reduce laboratory errors.

HGA-positive human serum from the Focus Diagnostics kit (Cypress, CA) served as a positive control for testing human sera, and three or five different diluted concentrations of rabbit sera were used for quality control of antigen slide because of the limited HGA-positive human sera. Rabbit sera against *A. phagocytophilum* and *E. chaffeensis* were prepared by immunizing rabbits with *A. phagocytophilum* (Webster strain) and *E. chaffeensis* (Arkansas strain), respectively. These two positive rabbit sera were serially twofold diluted and then assayed in parallel with human HGA-positive control sera from a Focus Diagnostics kit using the antigen slice prepared by our laboratory and a slide from Focus, respectively. Based on the quality control methods recommended by Focus Diagnostics, three or five different concentrations of diluted rabbit sera were screened as positive controls. The rabbit sera were frequently standardized using the Focus Diagnostics kit, especially when new batches of antigens were prepared. Two negative controls were selected for each IFA: PBS-milk and mixed healthy human sera (from five workers at our institute who were not members of our laboratory).

The IFAs were performed as follows. The serum samples were diluted 1:80 in PBS containing 3% nonfat powdered milk, and 25 μL of the diluted serum was placed in a slide well and incubated for 60 min in a moist chamber at 37°C. After washing in PBS to remove unbound antibody, the slides were labeled with FITC-conjugated rabbit anti-human immunoglobulin (IgG; Sigma Co., NY, New York State, United States) as a secondary antibody, which was diluted 1:400 with Evans blue, for another 60 min in a moist chamber at 37°C. The slides were then washed in PBS to remove unbound secondary antibody. The slides were air dried at 37°C and examined using a fluorescent microscope (Nikon, Tokyo, Japan). Samples were interpreted as reactive if there was strong green fluorescence corresponding to bacterial morulae within the cells on the slide. Samples reactive at the 1:80 screening dilution were considered to be positive [10, 12, 13]. If a serum sample had dual reactivity with *A. phagocytophilum* and *E. chaffeensis*, further dilution and titration were conducted, and a twofold or higher titer increase was read as positive.

2.5. Statistical Analysis. Statistical analysis was conducted using SAS software (version 9.1, SAS Institute, Inc., Cary, NC). Age was converted into a categorical variable (<10, 10–19, 20–29, 30–39, 40–49, 50–59, and ≥60 years of age). χ² and Fisher’s tests were used to compare distributions of seropositivity or to examine associations between pairs of categorical measures. Logistic regression analyses were used to calculate odds ratios (ORs) for seropositivity among variables. The survey questions regarding the variables “living in plains areas,” “living in hilly region,” “crop planting,” “planting fruit trees,” “livestock breeding or contact with domestic animals,” “length of working hours per day,” and “length of service time” were created to be associated with presumed risk among permanent residents of rural areas and to develop the explanatory variables used in the logistic regression. All tests were two-sided, and significance was set at less than 0.05.

3. Results

3.1. Study Areas and Population. A total of 7,322 rural residents from 57 villages in 33 rural counties in Zhejiang, Anhui, Jiangsu, Henan, Yunnan, Hainan, and Xinjiang provinces and from the cities of Beijing and Tianjin were investigated during March–May, 2009 (Figure 1). The mean age of the participants was 44 years (range, 2–81 years). Males accounted for 3,493 of the participants, with a mean age of 43 years (range, 2–80 years), and females accounted for 3,829 of the participants, with a mean age of 45 years (range, 2–81 years). In the rural areas investigated, 72% of participants lived in plains areas, and 28% of people lived in hilly regions. In total, 57% of residents were engaged in planting crops; 23% of residents were engaged in planting fruit; 4% of residents were engaged in feeding domestic animals; and 16% of investigated individuals were preschool children, students, or retired people. Additionally, 95% of residents had contact with domestic animals or livestock. Although 94% of people could recognize ticks and 12% of people recalled that they had been bitten by ticks before, nobody could tell the species of the ticks. In total, 6% of residents recalled fever (≥38°C), headache, or myalgia during the past year. Only 15% (65)
of people remembered the name of the antibiotics that they
had used, for example, a tetracycline (34), penicillin (15), a
cephalosporin (13), or a macrolide (3).

The characteristics of the 819 urban residents were as
follows: 310 sera (from males aged 18–25 years) were collected
from people who were ready to be drafted into the army in
Daqing city in 2007, Heilongjiang province, 98% of whom
were senior high school students, and 2% of whom were
young people waiting for job assignments. Another 256 sera
(from females aged 23–67 years) from Daqing were collected
from healthy people who had participated in a medical
examination in 2008. In addition, 253 sera (from 121 males
aged 18–76 years and 132 females aged 20–83 years) were
collected from healthy enterprise employees at a medical
examination center in Yanbian city, Jilin province, in 2008.
All of the people mentioned above lived in cities and rarely
engaged in work in the wild or were exposed to ticks.

3.2. Seroprevalence of E. chaffeensis. Values for the sero-
prevalence of A. phagocytophilum and E. chaffeensis in the
studied areas are shown in Table 1 and Figure 1. The overall
seroprevalence of E. chaffeensis was 9.8% (95% confidence
interval (CI) 9.1–10.5%) in rural residents and 2.4% (95%
CI 1.4–3.4%) in urban residents. Chi-square test analysis
indicated that the seropositivity rates of rural residents were
significantly higher than the rates of urban residents (P =
0.0001, OR 4.4, 95% CI 2.8–6.8%). In an IFA, 37 (0.45%)
samples exhibited a cross-reaction with A. phagocytophilum
and E. chaffeensis at a 1:80 cut-off, 16 (43%, 16/37) of which
were confirmed to be reactive with E. chaffeensis by further
titration. Among the seven provinces and two cities, the
seropositivity rates of E. chaffeensis of rural residents in
Xinjiang (43.2%, 95% CI 28.6–57.8%) and Hainan (44.6%,
95% CI 41.3–47.9%) provinces and Beijing city (19.4%, 95% CI
9.9–28.9%) were significantly higher compared with rates in
other areas. The difference in serological prevalence between
males and females in each province or city was not statisti-
cally significant (Table 2). Although age distribution differed
across age strata, the seroprevalence in the 20-to-29-year-
old (15.3%, 95% CI 13.5–17.1%) and 30-to-39-year-old (13.0%,
95% CI 11.4–14.6%) groups was significantly higher than in
the other age groups (P < 0.05) (Table 3). However, no
statistically significant difference was found between the two
groups mentioned above (P = 0.06). Of the seven provinces
and two cities in rural areas, the seroprevalence (44.6%,
95% CI 41.3–47.9%) was the highest in Hainan, followed by
Xinjiang (43.2%, 95% CI 28.6–57.8%) and Beijing (19.4%, 95%
CI 9.9–28.9%) (Table 2).

Regarding the variables associated with the presumed risk
based on the questionnaires, a statistical analysis indicated
| Area           | Province/ sampling year | Number positives/total number | M Seropositivity rate % (95% CI) | Number positives/total number | F Seropositivity rate % (95% CI) | Odds ratio (95% CI) | P value | Number positives/total number | M Seropositivity rate % (95% CI) | Number positives/total number | F Seropositivity rate % (95% CI) | Odds ratio (95% CI) | P value |

Table 2: The seroprevalence of *E. chaffeensis* and *A. phagocytophilum* by location and sex.
that fever in the last 24 months and service time >2 years were associated with the exposure risk of *E. chaffeensis*. However, no association between seroprevalence and other specific demographic variables was observed (Table 4).

### 3.3. Seroprevalence of *A. phagocytophilum*. The overall seroprevalence of *A. phagocytophilum* was 15.4% (95% CI 14.6–16.2%) in rural residents and 1.5% (95% CI 0.7–2.3%) in urban residents. The seroprevalence in rural residents was significantly higher than in urban residents (P < 0.0001, OR 12.7, 95% CI 7.2–22.5%). The seroprevalence varied between investigated sites, and the highest seroprevalence (41.8%, 95% CI 38.5–45.1%) of *A. phagocytophilum* was in Tianjin, followed by Hainan (39.2%, 95% CI 35.9–42.5%), Anhui (33.7%, 95% CI 39.5–40.2%), and Beijing (13.6%, 95% CI 3.5–23.7%) (Table 2). Analysis of sex indicated that the total seroprevalence of *A. phagocytophilum* in males (21.4%, 95% CI 20.0–22.8%) was significantly higher than in females (15.2%, 95% CI 14.1–16.3%) (P < 0.001, OR 1.5, 95% CI 1.3–1.7%). Similarly, the seroprevalence of *A. phagocytophilum* in the 20-to-29-year-old (20.2%, 95% CI 18.2–22.2%) and 30-to-39-year-old (25.3%, 95% CI 23.2–27.4%) groups was higher than in the other age groups (P < 0.05), although the seroprevalence varied between individual age groups.

Regarding associations between demographic characteristics and seropositivity, our data showed that the seroprevalence in residents who were engaged in planting crops was significantly higher than in people who were employed predominantly in fruit tree planting (P = 0.006, OR 0.8, 95% CI 0.7–0.9%). Similarly, the seroprevalence in residents who had contact with domestic and livestock animals was significantly higher than in residents without contact with animals (P < 0.0001, OR 4.0, 95% CI 2.6–6.3%). In addition, the seroprevalence in people who had worked for more than 2 years was higher than in people who had worked for less than 2 years (P < 0.0001, OR 1.8, 95% CI 1.5–2.1%). Additionally, fever in the last 24 months was associated with a high seroprevalence of *A. phagocytophilum* (P < 0.0001, OR 0.04, 95% CI 0.03–0.04%). However, no association was observed between tick bites and human infection, although tick exposure and bites were major risk factors for *A. phagocytophilum* and *E. chaffeensis* infections (P = 0.3, OR 1.1, 95% CI 0.9–1.3%).

### 3.4. Comparative Distribution of *A. phagocytophilum* and *E. chaffeensis*. Comparing the distribution of *A. phagocytophilum* and *E. chaffeensis*, the seroprevalence (33.7%, 95% CI 39.5–40.2%) of *A. phagocytophilum* in Anhui was strikingly higher than that of *E. chaffeensis* (5.5%, 95% CI 3.8–7.3%) (OR 0.12, 95% CI 0.08–0.2%). The same tendency was observed in Tianjin (OR 0.14, 95% CI 0.10–0.20%) (Table 5). In contrast, the seroprevalence of *E. chaffeensis* in Hainan (44.6% versus 39.2%, *P* = 0.03, OR 1.2, 95% CI 1.0–1.5%) and Xinjiang (43.2% versus 13.6%, *P* = 0.002, OR 4.8, 95% CI 1.7–13.7%) provinces and in Beijing city (19.4% versus 14.1%, *P* = 0.02, OR 1.5, 95% CI 1.1–2.0%) was significantly higher than that of *A. phagocytophilum* (Table 5).

### 4. Discussion

Regarding emerging zoonotic infectious diseases, increasing numbers of HGA cases have been confirmed in China since the unusual transmission of nosocomial cases of HGA occurred in Anhui province in 2006 [14, 16, 21]. Specifically, a case of coinfection with *A. phagocytophilum* and *E. chaffeensis* was reported in Shandong province [22]. A recent nationwide etiological investigation of HGA indicated that a total of 46 confirmed and 16 probable HGA cases were recorded from 2009 to 2010, and these cases were broadly distributed in Hebei, Shandong, and Henan provinces and in Beijing and Tianjin cities [21]. In this report, 41.2% of patients were diagnosed with multiple organ dysfunction syndrome.
Table 4: Analysis of the presumed risk of *E. chaffeensis* and *A. phagocytophilum* among rural residents.

| Variables                      | Total cohort | *E. chaffeensis* | *A. phagocytophilum* | OR   | 95% CI | *P* value | Total cohort | *E. chaffeensis* | *A. phagocytophilum* | OR   | 95% CI | *P* value |

Similarly, some isolates of tick were obtained from the human HGA isolates were obtained from patients, and one (M O D S ), and the fatality rate was as high as 8.1%. Four human HGA isolates were obtained from patients, and one tick isolate was obtained from the Haemaphysalis longicornis parasite on the bodies of the domestic animals owned by these patients. Among these HGA isolates, two human isolates and one tick isolate from Shandong Peninsula, where all of the patients exhibited severe clinical manifestations, were identical to each other, based on an analysis of 16S rRNA and the 16S rRNA gene of the five Chinese isolates mentioned above might impact the seropositivity in these animals and ticks indicated that the dominant group, which consisted of 59.2% of the sequences from the domestic animals and 67% of the sequences from the ticks, was grouped with the sequences of the two human Chinese HGA isolates from Shandong province, mentioned above [21]. Moreover, the sequences (EF211110) identified in a patient with a nosocomial infection in Anhui in 2006 and the sequences (EU982709) from a patient in Yiyuan county, Shandong province, in 2007, were classified into the group [5]. The geographic distribution of A. phagocytophilum was mainly in Hainan, Anhui, Tianjin, and Beijing (Table 2). Hainan province is the second largest island in China, and its climate characteristics are advantageous to vector-borne rickettsial diseases. A retrospective field investigation on rickettsioses in Chengmai county, Hainan province, revealed that 5% of farmers’ houses contained ticks, and a tick blood trail could be observed on the walls of the houses. Additionally, 15% of local children (40/270) had a typical eschar or rash on their bodies. A total of 11 isolates of rickettsiae were isolated from 23 febrile patients, and seven isolates of rickettsiae were isolated from wild Rattus flavescent, which were captured in local areas. The field investigation indicated that the seroprevalence was 6.3% (51/812) for A. phagocytophilum, 12.5% (101/812) for E. chaffeensis, and 37.5% (305/812) for spotted fever rickettsia in the local population [23]. PCR amplification of the 16S rRNA genes of rickettsiae in tick samples indicated that the positive rates were 23.3% (7/30 sample pools) for R. sanguineus, 6.9% (2/29 sample pools) for H. denviti, and 12.7% (9/71 sample pools) for R. microplus [23]. Anhui province is located in the middle of the eastern
part of China and an unusual outbreak of anaplasmosis occurred in a hospital in this province in 2006. In a previous study, we focused on investigating Guanxue county, where the index patient from the nosocomial transmission of HGA lived; Huaiyuan county; and Mingguang county. The results demonstrated that the average seropositivity rate of *A. phagocytophilum* among rural residents was 33.7% (201/596) [24]. Of the three sites investigated, Guanxue county had the highest seroprevalence (76.5%, 153/200) and Huaiyuan county had the lowest (10.4%, 26/249). Tianjin CDC conducted a seroprevalence (76.5%, 153/200) and Huaiyuan county had the largest countries in the world and had complex ecological system and each province had different geographic and climatic characteristics. It is reported that Xinjiang province alone had more than 50 species of ticks [35].

For analysis of proposal transmission vector of *A. phagocytophilum* in China, an epidemiological field investigation found that there were many ticks on the bodies of animals, and at least six species of ticks were identified. PCR amplification of *A. phagocytophilum* 16S rRNA showed that the positive rates were 58.3% for *Dermacentor silvarum*, 43.9% for *Haemaphysalis longicornis*, 12.5% for *Ixodes persulcatus*, 7.5% for *Rhipicephalus microplus*, and 5.2% for *Rhipicephalus sanguineus* [5]. More molecular investigations indicated that *Ixodes persulcatus*, *Dermacentor silvarum*, *Haemaphysalis concinna*, *Haemaphysalis longicornis*, *Rhipicephalus microplus*, *Rhipicephalus sanguineus*, and *Dermacentor nuttalli* might transmission of *A. phagocytophilum* in China [5, 23, 27, 29, 36]. Notably, such more species of ticks carrying *A. phagocytophilum* organisms in China were different from those found in USA. Whether this phenomenon was associated with some genetic variations of Chinese HGA isolates mentioned above remained to be further explored.

Additionally, some recent researches showed that several kinds of domestic animals including dog, goats, sheep, cattle, horse, wild rabbit, and some small wild rodents including *Apodemus agrarius*, *Tamias sibiricus*, *Apodemus peninsulae*, and *Gerbillus* spp. are the dominant species in ticks collected from Xinjiang province [26] and from countries neighboring China [28].

The sex distribution varied between the areas investigated, but male farm residents are at a higher risk of infection with *A. phagocytophilum* than females when considering the total population studied, although no differences were observed between males and females for *E. chaffeensis*. An analysis of the age distribution indicated that the highest seroprevalence of *E. chaffeensis* and *A. phagocytophilum* was identified in the 20-to-29-year-old and 30-to-39-year-old groups (Table 3). We presumed that this phenomenon was due to more outside activities among these young people.

Our current findings and previous data provide strong evidence that *A. phagocytophilum* and *E. chaffeensis* exist in China, and the seroprevalence of urban residents were lower than that of rural residents, we had to address that the results in the study might be affected by the geographic characterizes [33, 34]. The urban samples were collected from Daqing city of Heilongjiang and Yanbian county of Jilin provinces, which located in the northeast of China and shared cooler climate, especially Daqing areas characterized with sterile saline and alkali soil with rare vegetative cover was not conductive to the breeding of ticks.

More and more researches indicated that the distribution of tick-borne pathogens [33, 34]. China is one of the largest countries in the world and had complex ecological system and each province had different geographic and climatic characteristics. It is reported that Xinjiang province alone had more than 50 species of ticks [35].

Because human monocytic ehrlichiosis (HME) is an emerging tick-borne infectious disease, seroepidemiological information about HME is limited in China. This study serologically demonstrated a higher prevalence rate of *E. chaffeensis* among farm residents in Hainan (44.6%, 95% CI 41.3–47.9%), Xinjiang (43.2%, 95% CI 28.6–57.8%), and Beijing (19.4%, 95% CI 9.9–28.9%) (Table 2). Additionally, Hainan and Xinjiang provinces shared a higher coprevalence of *E. chaffeensis* and *A. phagocytophilum*. Xinjiang province, located in central Asia and neighboring Mongolia, Russia, and Kazakhstan, is famous in China for numerous tick species. Many studies have identified *E. chaffeensis* in ticks collected from Xinjiang province [26] and from countries neighboring China [28].
investigated to better understand the pathogenesis of these pathogens, especially the relationship between the general-ized susceptibility of vectors and reservoirs, the severity of the disease's clinical manifestations, and the genetic variation of Chinese HGA isolates in China.

In summary, the tick born rickettsial diseases caused by *A. phagocytophilum* and *E. chaffeensis* have become a serious threat to human and animal health. Several measures should be taken to minimize the likelihood of becoming infected with these two zoonotic rickettsiae from direct contact with farm animals, especially among individuals who work with livestock. The health management department should emphasize the differentiation of these zoonotic infectious diseases from other febrile diseases, especially for the prevention and control of nosocomial human-to-human transmission, during treatment.
