Visual Abstract

Economic decisions arise from evaluation of alternative actions in contexts of motivation and memory. In the predatory sea-slug Pleurobranchaea the economic decisions of foraging are found to occur by the workings of a simple, affectively controlled homeostat with learning abilities. Here, the neuronal circuit relations for approach-avoidance choice of Pleurobranchaea are expressed and tested in the foraging simulation Cyberslug. Choice is organized around appetitive state as a moment-to-moment integration of sensation, motivation (satiation/hunger), and memory. Appetitive state controls a switch for approach vs. avoidance turn responses to sensation. Sensory stimuli are separately integrated for incentive value into appetitive state, and for prey location (stimulus place) into mapping motor response. Learning interacts with satiation to regulate prey choice affectively. The virtual predator

Significance Statement

Contemporary artificial intelligence lacks the attributes of natural intelligence, in particular the abilities to relate information affectively. Accordingly, it is notable that the most complex animal behaviors serve primitive homeostatic goals, and emerge from the primitive mechanisms generating motivation and reward learning. Here is shown in simulation the function of a basic neuronal circuit for cost-benefit decision, derived from studies of a predatory generalist, the sea-slug Pleurobranchaea, and based on affective integration of information. Its simplicity may reflect distant ancestral qualities on which complexities in economic, cognitive, and social behaviors were built. The simulation validates experimental data and provides a basic module for expansion of behavioral complexity.
realistically reproduces the decisions of the real one in varying circumstances and satisfies optimal foraging criteria. The basic relations are open to experimental embellishment toward enhanced neural and behavioral complexity in simulation, as was the ancestral bilaterian nervous system in evolution.

Key words: decision; homeostasis; learning; motivation; pleurobranchaea; simulation

Introduction
Foraging behavior in tracking and consuming resources is a series of economic decisions guided by stimulus characters predictive of risk and resource value. The basic behavioral choice is between an approach or avoidance of salient stimuli, a cost-benefit calculation done through integrating stimulus properties with motivation and memory. However, the natural intelligence displayed by even the simplest foraging animals has remained to be captured fully in artificial intelligence constructs in terms of actual neural computations made by real animal foragers.

We undertook to implement and test a model of foraging decision derived from the neuronal circuitry underlying approach-avoidance decisions in the predatory sea-slug *Pleurobranchaea*. The neuronal circuitry of decision has been characterized down to the single-neuron level (Gillette et al., 1982; London and Gillette, 1986; Jing and Gillette, 2000, 2003; Hirayama and Gillette, 2012; Hirayama et al., 2012, 2014). In particular, a key decision mechanism was found to lie in regulation of the turn motor network by the feeding network, whose excitation state depends on sensory input, memory, and satiation. Sufficient excitation in the feeding network converts default avoidance responses to sensory stimuli to approaching turns (Hirayama and Gillette, 2012). These findings localized motivation, appetitive state, and control of motor decision to the feeding network. They also account for behavior in which (1) quite hungry specimens not only orient to and bite at weak appetitive stimuli, but will also attack moderately noxious stimuli; (2) appetitive thresholds for approaching turns rise proportionately with satiation; and (3) as satiation increases, the animals avoid increasingly strong appetitive stimuli (Gillette et al., 2000; Noboa and Gillette 2013). Further, motor choice in *Pleurobranchaea*‘s learned discrimination of odors paired with unconditioned stimuli (USs) is also mediated at the feeding motor network level (Davis et al., 1980; Mpitsos and Cohan, 1986a; Noboa and Gillette, 2013). These relations indicate a simple neural model for cost-benefit-based decision in the animal’s foraging (Gillette et al., 2000; Hirayama et al., 2012).

The simulation Cyberslug implements the integrated model in an autonomous agent with behavior designed from neurophysiological and behavioral data. To our knowledge no other such empirically driven neuroeconomic simulation has yet been devised. The success and utility of Cyberslug are supported through its accurate and dynamic reproduction of functional relations in *Pleurobranchaea*‘s nervous system and behavioral repertory, its ability to maintain the fitness (here, nutritional state) of a virtual predator through plausible choices of differently valued prey based on hunger state, sensation, and memory; and its capacity to weigh risk against resource value to optimize foraging decisions.

Materials and Methods
Software accessibility
Cyberslug is freely available as extended data online at https://github.com/Entience/Cyberslug.

General design of biological relations
Sigmoidal relations are used as constructive approximations to simulate biological processes that accelerate from small beginnings to saturate at high values. They or their influential values appear in Equations 3.0, 5.1, 6.0, 7.1, 7.2 to compute virtual place codes for sensory stimuli, appetitive stimulus affect, satiation, appetitive state, a behavioral switch based on appetitive state, and the amplitude of a turning response, respectively. Centers and asymptotes may be graphed for the interested reader from the values given in the source code.

Learning
Reward and punishment associations are formed with the prey sensory signatures, odor_hermi and odor_flab, using the Rescorla-Wagner algorithm for classical conditioning (Rescorla and Wagner, 1972):

\[
\Delta V = \alpha \ast \beta (\lambda - V).
\]  

(1)

On a given trial the change \(\Delta V\) in the predictive value of a stimulus \(V\) (the amount of learning) depends on the difference between the value of what actually happens, \(\lambda\), and what is expected (or already learned), \(V\). The \(\alpha\) term is the salience constant (the attention-getting capacity) of the conditioned stimulus (CS; ranging from 0 to 1, and set
here at 0.5 for both odor_hermi and odor_flab). The β term is a rate parameter for the associative capacity of the US with the CS (ranging from 0 to 1; here a maximum of 1). The λ term is the maximum associative value of the US (set at 1 for odor_hermi and odor_flab). The Rescorla-Wagner algorithm was selected for its intuitive layout, simplicity, and robustness in a range of learning applications (Danks, 2003; Rasmussen et al., 2015). It is a useful approximation of learning from insects to mammals (Miller et al., 1995).

Sensory transduction and integration

The Cyberslug agent uses bilaterally paired, anterior odor sensors, simplifying the real animal’s chemotactile oral veil’s function in prey tracking (Yafremava et al., 2007). The sensors report strengths of the three odors at slightly less than half a body length in front of the agent and at a roughly 40° angle with respect to its anteroposterior axis. For example, in the case of betaine, the averaged odor strength is

\[ sns_{betaine} = \frac{sns_{betaine\_left} + sns_{betaine\_right}}{2}, \]  

where \( sns_{betaine\_left} \) and \( sns_{betaine\_right} \) are logarithmic functions of betaine virtual concentrations at each sensor. The \( sns_{betaine} \) variable integrates into the appetitive stimulus effect (Eq. 4.2).

The Somatic_Map function transforms sensory input into a virtual place code of the estimated direction of the strongest odor. It includes a mechanism emphasizing the salience of the nearest prey, analogous to surround suppression mechanisms underlying attention (Boehler et al., 2009): when closer to one prey type, sensation of the other is decreased, which reduces consumption of the aversively learned Flab in the presence of the odor of Hermi. The output of Somatic_Map is a template for the turn amplitudes of resulting approach-avoidance responses:

\[ Somatic\_Map = \left[ \frac{sns_{flab\_left} - sns_{flab\_right}}{1 + e^{-k_{F} F}} \right] + \left[ \frac{sns_{hermi\_left} - sns_{hermi\_right}}{1 + e^{-k_{H} H}} \right] \]  

where

\[ F = sns_{flab} - sns_{hermi} \]  

and

\[ H = sns_{hermi} - sns_{flab}. \]  

The incentive variable (Incentive) integrates sensory information of positive and negative valences. It represents the incentive potential of a stimulus as modulated by learning and motivation:

\[ Incentive = R^+ - R^-, \]  

where \( R^+ \) and \( R^- \) represent appetitive and aversive stimulus affects, respectively:

\[ R^+ = \frac{sns_{betaine}}{1 + k_{1} \cdot V_{n} \cdot sns_{hermi}} + k_{3} \cdot V_{n} \cdot sns_{hermi} \]  

(4.2)

\[ R^- = k_{3} \cdot V_{n} \cdot sns_{flab} \]  

(4.3)

Satiation and appetitive state

Hunger state is represented through the function Satiation, which reflects Nutrition in a sigmoid relation with a lower bound near 0 and an upper asymptote at 1:

\[ Satiation = \frac{1}{1 + k_{4} e^{-4 \cdot Nutrition_{t}^{2}}} \]  

(5.1)

where Nutrition, without prey consumption, decreases recursively with each time step:

\[ Nutrition_{t+1} = Nutrition_{t} - 0.0005 \cdot Nutrition_{t}, \]  

(5.2)

When feeding occurs, Nutrition is increased by a value of 0.3. The simulation initializes with Nutrition set at 0.8. Appetitive state (App_State) is a function of Incentive and Satiation. It defines the thresholds for decisions to approach or avoid given prey items. It parallels expression of appetitive state in the excitation of Pleurobranchaeas’s feeding network (Hirayama and Gillette, 2012). The sigmoidal element increases App_State as Incentive increases and decreases it as Satiation increases. As in the real animal, App_State is transiently suppressed during avoidance turning (J.W. Brown, V. Noboa, and R. Gillette, unpublished observations). This acts to further bias decision away from approach during the avoidance turn when some appetitive sensory input is present:

\[ App\_State = 0.01 + \frac{1}{1 + e^{-k_{5} \cdot Incentive + k_{6} \cdot Satiation}} + k_{7} \cdot (App\_State\_Switch - 1), \]  

(6.0)

where the expression (App_State_Switch – 1), defined and discussed later, causes a transient suppression of App_State during avoidance turns. It may be noted that satiation state is a variable in both Incentive and App_State, which reflects findings that satiation state is expressed in the basal excitation state of the feeding network, and that satiation may modulate sensory gain in the periphery (V. Noboa, T. Achler, and R. Gillette unpublished observations). The satiation term dominates App_State values at its extreme ranges (0 and 1). Incentive is significant in the mid-range, as in Pleurobranchaeas (Gillette et al., 2000). When satiation is either very low or high, it dominates over the incentive term. When very low, the Cyberslug agent
chooses to consume the previously learned, noxious Flab. When very high, it actively avoids otherwise appetitive Hermis. These choices reproduce those made by very satiated or hungry Pleurobranchaea (Gillette et al., 2000; Noboa and Gillette, 2013).

Turning and locomotion

The function \( \text{App\_State\_Switch} \) switches the turn motor network from avoidance to approach, representing the ASw1,2 actions of Figure 2. It acts like the corollary outputs from Pleurobranchaea’s feeding network that toggle the turn motor network polarity (Brown, 2014). The function converges steeply to either 1 or -1 depending on the value of \( \text{App\_State} \):

\[
\text{App\_State\_Switch} = \frac{-2}{1 + e^{-k8 (\text{App\_State} - 0.245)}} + 1, \quad (7.1)
\]

In particular, when \( \text{App\_State} \) goes below or above a threshold, set here as 0.245, \( \text{App\_State\_Switch} \) approaches 1 or -1, respectively, to govern turn direction. This threshold might well be a variable influenced by reproductive state, health, or neuromodulatory inputs from other neuronal networks (cf Hirayama et al., 2014), but is set as a simple constant here.

The turn is computed in degrees as:

\[
\text{Turn\_Angle} = \frac{k9 \cdot \text{App\_State\_Switch}}{1 + e^{k3 \cdot \text{Somatic\_Map}}} - \text{App\_State\_Switch}, \quad (7.2)
\]

where positive or negative values of \( \text{App\_State\_Switch} \) cause avoidance or approach turns, respectively. Sufficient excitation in the Feeding Network (when \( \text{App\_State} \) is >0.245) switches the polarity of an elicited turn from default avoidance to an approach turn. A sensory place code (somatic map) for stimuli provides a template for turn response amplitude in both approach and avoidance. Negative feedback to the feeding network from the turn network during avoidance transiently suppresses feeding, while feeding network activity is reduced as satiation increases. The model is modified from Gillette et al., 2000; Hirayama et al. 2012.

**Figure 1.** Approach-avoidance modeling in Pleurobranchaea. Appetitive state (excitation of the feeding network) summates intrinsic and learned stimulus values (incentive) with satiety to regulate turn response direction. In parallel, a somatotopic map of a stimulus in the animal’s oral veil sets the turn trajectory. Incentive sums sensory inputs predicting intrinsic nutritional value (resource signal) and the learned positive and negative values of prey odor signatures (\( R^+ \) and \( R^- \)). The positive or negative consequences of attacking the different prey are learned through instructive feedback from the feeding network. In the absence of incentive, basal appetitive state simply represents the animal’s satiation state (a negative feedback from prey capture). At some threshold, feeding network outputs change the turn motor response to a stimulus from default avoidance to an approach turn. A sensory place code (somatic map) for stimuli provides a template for turn response amplitude in both approach and avoidance. Negative feedback to the feeding network from the turn network during avoidance transiently suppresses feeding, while feeding network activity is reduced as satiation increases. The model is modified from Gillette et al., 2000; Hirayama et al. 2012.

**Results**

The core model

Cyberslug is based on neuronal relations of approach-avoidance decision in Pleurobranchaea’s responses to odors of potential prey (Gillette et al., 2000; Hirayama and Gillette, 2012). Figure 1 shows the flow of information, from initial feature extraction of different sensory inputs to their evaluation in terms of estimated total resource value (incentive), based on nutritional need and memory; these processes then direct motor output for approach or avoidance turns. Figure 2 shows the logic of the model’s implementation into Cyberslug. The relations are represented in simple equations that drive the agent. Values of
The constants ($K_c$) in the equations were optimized over numerous trials and are found in the NetLogo code available as extended data. Altering the values in the code may lend appreciation for the role of natural selection in adaptively tuning neural circuitry.

Foraging decision is controlled by appetitive state. The animal’s feeding motor network is at the core of the decision module. Its excitation state directs choice between approach and avoidance turns (Hirayama and Gillette, 2012). The excitation state manifests the appetitive state of the animal; i.e., the disposition to engage in goal-directed appetitive behavior. Appetitive state integrates the animal’s satiation state, sensation, and memory of experience (Davis and Gillette, 1978; Davis et al., 1980; London and Gillette, 1986; Gillette et al., 2000; Hirayama and Gillette, 2012). Satiation determines the baseline excitation state of the feeding network. Incoming sensory inputs are integrated with memory into incentive. Incentive sums with satiation in the feeding network, either increasing or decreasing appetitive state.

By default, when appetitive state is low, the animal’s nervous system is organized so that the turn response to any sensory stimulus is avoidance. During the aversive turn appetitive state is decreased by inhibitory inputs in the feeding network (Davis and Gillette, 1978; London and Gillette, 1986; Hirayama and Gillette, 2012; Brown, 2014). Increasing appetitive state inverts the turn response direction to one of approach. Thus, appetitive state determines the sensory thresholds for the approach turn toward a prey and subsequent feeding responses. When high enough, corollary outputs from the feeding network appear to switch the excitatory sensory input-encoding stimulus site from one side of the turn network to the other, resulting in a turn toward the stimulus (Brown, 2014).

Sensory inputs here are of four kinds: (1) a resource odor signal predicting nutritional content to Pleurobranchaea, the amino acid betaine (Gillette et al., 2000); (2) a specific odor signature for a particular prey species (Noboa and Gillette, 2013); and (3) a place code for the averaged site of sensory input to the sensors (Yafremava et al., 2007; Yafremava and Gillette, 2011). (1) and (2) are summed as Incentive for resource and learned positive and negative values of prey odors ($R^+$ and $R^-$, respectively), which is then integrated with motivation (satiation) as appetitive state in the feeding network. The somatic map variable embeds (3) as a template for turn response amplitude. Positive or negative classical learning are assumed consequences of feedback from the feeding network operating in feeding or avoidance modes, respectively.

The Cyberslug simulation preserves the basic interactions of feeding and turn networks in the control of the turn by appetitive state and aversive suppression of the feeding network. Simplifications include: (1) for learning, explicit pain mechanisms are omitted in favor of arbitrary consequences; (2) exploratory locomotion is the default action in absence of active avoidance or approach; and (3) the switch mechanism for turn direction is rendered as a sigmoidal equation.

**Cyberslug environment**

Cyberslug is implemented in the graphic modeling, agent-based programming language NetLogo 5.3.1. (Wilensky, 1999). Agent actions and odor diffusion are executed in discrete time steps by underlying code, where agents run commands in a turn-taking mechanism to simulate concurrence. At each time step the agent positions, orientations, speeds, and odor intensities in individual patches are updated with the variables that control them.

The interface screen (Fig. 3) displays current values of agent-associated variables and statistics. Users may override automatic agent navigation by manually controlling these agents with the mouse, specify the number of prey objects in the environment, and switch on or off a function that traces the agent’s path. When the simulation is initialized, a single Cyberslug agent and the different prey are generated at random positions in the environment.

**Prey**

The Cyberslug agent encounters two virtual prey, “Hermi” and “Flab,” after the sea-slugs *Hermissenda crassicornis* and *Flabellina iodinea*, which *Pleurobranchaea* can encounter in the wild (Noboa and Gillette, 2013). These are shown

---

*Figure 2.* Logical flow in the Cyberslug model. Sensory inputs (SNS) for resource signal odor (Bet) and learned values of prey odor signatures (Flab and Hermi) are integrated into Incentive and summate with Satiation in appetitive state (App_State). Sensory somatotopic place information is encoded in somatic map, which acts as a template for the turn response amplitude. The turn motor network responds by default to sensory input with an avoidance turn response unless input from App_State is high enough to switch the turn to approach; this is mediated directly by a simple dyadic disinhibitory switch (ASw$_{1,2}$). Successful predation increases satiation which in return reduces App_State.

---

*January/February 2018, 5(1) e0400-17.2018*
Figure 3. Screenshots of the Cyberslug environment and interface. Frames are shown from early (upper) and later (lower) in a software run. The Cyberslug agent (orange) encounters Hermi (green orbs) and Flab (red orbs) in its environment and traces its path (orange contours). Users can select the number of prey in the environment, move Cyberslug manually, or toggle the path tracer. Various Cyberslug and environmental parameters are updated in real time, as shown. In the early frame, the Cyberslug is orienting toward prey (App_State /H11005/ 0.545, high; App_State_Switch /H11005/H11002/ 1), and in the later frame, it is in aversive mode (App_State /H11005/ 0.029, low; App_State_Switch /H11005/H11001/ 1).
as small orbs, colored green for Hermi and red for Flab. Each prey secretes two odors: the resource signal betaine, a predictor of nutritional resource (Gillette et al., 2000), and either of “odor_hermi” or “odor_flab.” Odors diffuse over time and space as for actual diffusion. Prey move in a simple random walk. Prey numbers remain constant; when consumed, replacements appear at random positions.

The specific odors of Hermi and Flab become associated with preference and avoidance, respectively, through reward learning. These effects are analogous to the ready consumption of Hermissenda by Pleurobranchaea, and the rejection and aversive learning of Flabellina (Noboa and Gillette, 2013). A Batesian mimic, “Faux-Flab,” is included as an option. In Nature, Batesian mimics receive protection from predation by mimicking appearance or odor of noxious species, and by their presence may increase attempted predation on the noxious species. Thus, Faux-Flab has the odor of Flab and the positive rewarding qualities of Hermi. The mimic is included for the user to test its effects on predator choices.

The Cyberslug agent

Reward and punishment associations are formed with the prey sensory signatures using the Rescorla-Wagner algorithm for classical conditioning (Rescorla and Wagner, 1972), allowing the predator to learn through experience. Bilaterally paired, anterior odor sensors simplify the real animal’s chemotactile oral veil’s function in prey tracking (Yafremava and Gillette, 2011) to report the strengths of odors for betaine, a predictor of nutritional value, and the prey signature odors for Hermissenda and Flabellina. The sensors also transform sensory input into a virtual place code, giving the estimated direction of the source of the strongest odor, on which motor response is patterned. The incentive of an odor is calculated as summed positive and negative valences, which are determined by the intrinsic appetitive nature (for betaine) and learning experiences for the signature odors.

Appetitive state is the final regulator of behavioral choice. It summates incentive with satiation, and thus integrates sensory stimulus qualities with learning and motivation. Satiation is a simple function of nutritional state, which declines over time following prey consumption. Satiation dominates appetitive state at its extreme ranges (quite hungry or not); whereas stimulus incentive is significant in the mid-range. At a threshold value, appetitive state causes a directional switch between approach or avoidance in the turn response to an odor. The choices made reproduce those seen across the spectra of learning and hunger state by Pleurobranchaea (Gillette et al., 2000; Noboa and Gillette, 2013).

Testing the simulation

Cyberslug was tested for prey selectivity as modified by learning, motivational state, and their interactions. Four sets of six tests were run under conditions assessing effects of learning and satiation mechanisms on prey selection. Effects of satiation and learning on selectivity were tested in arenas containing (1) 10 Flabs and 3 Hermis; (2) 13 Flabs alone; and (3) 13 Hermis alone. Tests ran for 150,000 software time steps.

Results in Figure 4 show that in the 10 Flab/3 Hermi arena satiation acted to limit the numbers of prey consumed. Without either mechanism for learning or satiation, selectivity was low, and prey were consumed as encountered in the 10 Flab/3 Hermi arena. Adding learning mechanisms did not alter either selectivity or number of prey consumed. When satiation was present without learning, prey consumed dropped, but selectivity was unchanged. When both learning and satiation mechanisms operated, selectivity was high and total prey consumed dropped to even lower values [one-way ANOVA across the four behavioral scenarios, \( p < 0.0001; ***p < 0.001 \) relative to all other learning/satiation scenarios (Tukey-Kramer, \( n = 6 \) trials in each)]. Differences in selectively between the first three learning/satiation scenarios, or in prey consumption where satiation was inactivated, were not significant (\( p > 0.05 \)) Error bars are SEM. See text for further explanation.
Between the two satiation and two no-satiation scenarios, while enhancement of prey selectivity depended on learning and satiation acting together. Thus, in tests where both learning and satiation mechanisms were inactivated, average total prey taken was 701 (SEM 6.22), of which 21.2% (SEM 0.6%) were Hermis, slightly less than their 23.1% frequency in the population. This yielded a selectivity value (total Hermis taken/total Flabs taken) of 0.27 (SEM 0.01), less than the 0.30 ratio of Hermis to Flabs in the population. This effect appeared due to a greater frequency of random clustering in the denser Flab population, leading to more frequent multiple consumptions of Flabs than Hermis. When learning was activated without satiation, average total prey taken was still high at 707.8 (SEM 5.5), of which 21.2% (SEM 0.6%) again were Hermis with still a low selectivity of 0.27 (SEM 0.01). Without learning, satiation alone reduced average prey consumed to 119 (SEM 0.52) with 24.1% (SEM 1.2%) Hermi, and with low selectivity of 0.32 (SEM 0.02).

Acting together, learning and satiation mechanisms led to an averaged total of 91.7 (1.43 SEM) prey taken, where 82.5% (SEM 1.5%) were Hermi. The selectivity coefficient of 4.96 (0.6 SEM) was a >18-fold increase over the values obtained without learning and/or satiation.

When tests were made in a field of 13 Flabs alone, with both learning and satiation intact, the averaged total prey taken was 53.3 (0.33 SEM). This low but nontrivial value reflected decisions to take noxious prey in a condition of extreme hunger, and also demonstrated combined effects of learning and satiation in reducing consumption of noxious prey (not shown). When similar runs were made in a field of 13 Hermis alone, the averaged total prey taken was 143.5 (0.81 SEM). The contrast of this value with the all Flab condition highlighted effects of positive versus negative learning in prey selection, as well as effects of satiation in limiting consumption. There were significant differences in number of prey consumed across all three arenas (p < 0.0001 in a one-way ANOVA; Tukey-Kramer, p < 0.001, among all three pairs).

**Discussion**

The Cyberslug autonomous entity bases behavioral choice and perception on interactions of motivational state and learning, like the real animal. The algorithmic integration of sensation, motivational state, and memory reproduces adaptive action selection in behavioral choice. At intermediate values of satiation, the experienced Cyberslug agent selectively prefers or avoids the cues of benign or noxious prey, respectively. Otherwise, at lower levels of satiation (greater hunger) the predator is attracted to and consumes previously learned noxious prey. Accordingly, to forestall starvation it is economically realistic and in agreement with optimal foraging models that selectivity declines with decreasing satiation (Houston and McNamara, 1985). At higher satiation it actively avoids even the stronger appetitive signals. In these behaviors the simulation agrees with the classic, inverted U-shaped function relating arousal state to performance (Hebb, 1955), and reproduces major behavioral aspects of the real predator (Gillette et al., 2000; Noboa and Gillette, 2013).

The individual contributions of satiation and learning are naturally significant. However, the importance of their interactions in prey choice is well illustrated (Fig. 4). Without either one of satiation and learning, the unrestrained virtual predator takes in great quantities of either prey. This can be maladaptive to a real predator, where taking more high-quality prey than safely handled by digestion is physiologically threatening. Satiation limits the number of prey taken, but without learning noxious prey species are taken indiscriminately. Learning prey values promotes specific exploitation of the benign species and reduces attempts on the noxious species to periods of near-starvation, when a potential small benefit could be important to survival.

In Cyberslug, as in Pleurobranchaea, appetitive state is the continuous integration of sensation, internal state, and memory, and it sets the thresholds for expressing goal-directed behavior. Cyberslug summates the variables as appetitive state in the core Equation 6 to yield output that can switch avoidance responses to approach. Sensory integration in the model accomplishes two critical actions: evaluating the sensory stimuli as incentive, and providing a spatial map of stimulus location. Thus, incentive sums the primary odor nutritional signal (betaine) with positive and negative qualities learned from previous encounters with the initially neutral, specific odor signatures of its prey (Eq. 4.1).

In the absence of incentive input to the feeding network, appetitive state is solely dependent on the motivational variable satiation. However, with incentivized sensory input appetitive state becomes equivalent to “incentive salience” as defined in rodents and primates (Berridge and Robinson, 2016), where goal-oriented desire becomes tightly linked to reward cues and is critical to establishing preferences. The fuller concept of “motivational salience” regulating the attraction or aversion to objects in mammals (Puglisi-Allegra and Ventura, 2012) emerges in the present model with regulation of the approach-avoidance switch by appetitive state. Thus, the model illustrates how the salience of a stimulus may interact with motivational state and learning to determine its attractiveness or aversiveness.

Stimulus mapping is analogous to that done in the peripheral nervous system of the animal’s oral veil (Ya-fremava and Gillette, 2011): a virtual place code represents the averaged location of an odor stimulus as Somatic_Map, and incorporates an analog of lateral inhibition as seen in the animal (Eq. 3.1). This provides a template to map the motor output of the turn angle response, much like functions of superior colliculus and cortex in vertebrates.

Cyberslug implements essential elements of an affectively controlled, primitive type of immediate (or “anoetic,” unknowing) consciousness (Tulving, 1985) whose experience is largely a moment-to-moment event. It is a rudimentary form postulated as an evolutionary precursor to higher conscious functions of self-awareness in contexts of semantic and episodic memory (Tulving, 1985; Denton et al., 1999; Vandekerckhove and Panksepp, 2011; Vandekerckhove et al., 2014). In more com-
plex animals, the simple immediate consciousness persists in the subpallial mechanisms that generate moti-
vation and reward to drive homeostatic behavior, and
which thereby sustain and direct the higher cognitive
functions (Vandekerckhove and Panksepp, 2011). The
rules governing choice in Pleurobranchaea and Cyberslug
could resemble a core type of decision module present in
ancestors of the major bilaterian lineages, before the evo-

eolution of the complex brains and behaviors that accom-
panied segmentation, articulated skeletons, and greater
behavioral involvement in reproduction (Gillette and
Brown, 2015). In the vertebrates, control of approach-
avoidance decision is a basic function of the basal ganglia
and hypothalamus. In arthropod nervous systems, these
functions are performed by antennal lobes and mushroom
bodies, which may conserve homologous structures as
well as analogous functions (Strausfeld and Hirth, 2013).
The feeding network in Pleurobranchaea combines func-
tions of vertebrate hypothalamus and basal ganglia for
motivation, incentive comparison, and selection of mo-
tor actions. The more complicated and modularized cir-
cuities in vertebrates and arthropods reflect more

complex bodies and lifestyles, but their brains were likely
built onto a basic structure as shown here.

Little previous evidence has been found for empirically
driven neuroeconomic simulations such as this one. How-
ever, it is notable that the innovative 1996 videogame
Creatures used a bottom-up approach to AI character
development, combining basic concepts of motivation
and drive with Hebbian-like learning mechanisms in large
artificial neural networks to achieve interesting behavior.
This simulation is designed for transparency and interac-
tiveness. Users may discover diverse, and perhaps unex-
pected, emergent properties for forager decision and prey
vulnerability by altering their densities, particularly with
the Batesian mimic, and by altering properties in the code.

The simple relations on which Cyberslug runs are read-
ily adaptable to faster-executing computer languages,
fine graphics, artificial neural networks, and neuromorphic
representations. The present simple presentation of Cy-
erslug’s behavior in real time is intended to offer ready
accessibility to a broad audience. The core decision mod-
ule is open to practical improvements in learning algo-
rithms, including addition of mechanisms for behavioral
habituation and sensitization. More potential is present;
for instance, the model embodies an essential character
of the addictive process in incentivization, and might with
little modification reproduce the sequelae of addiction,
withdrawal, and cravings.

The homeostatic circuit relations underlying hunger
drive in Cyberslug and Pleurobranchaea are adaptable to
acquiring other resource types, such as hydration, salt
balance, shelter, play, and social interactions, to name a
notable few common to vertebrates. Truly intelligent
and sentient virtual entities, defined in terms of empathic
communication and abstract thought, may not yet exist be-
cause they lack the constellation of autonomy, motivation,
valuation, emotion, and social awareness (cf. also
Minsky,
2006). Of these, Cyberslug supplies essential aspects of
autonomy, biologically based motivation, and valence
assignment. It is reasonable that cognitive and social
features might be added in simple piecemeal fashion follow-
ing an evolutionarily plausible course, guided by
comparative reference to invertebrate and vertebrate spe-
cies that vary incrementally in their cognitive and social
expressions with complexity of lifestyle. Of necessity in
evolution, most valuation and decision processes in the

economies of complex social animals would have been
elaborated onto pre-existing, simpler decision modules
for homeostasis, like those of Pleurobranchaea and other
simple invertebrate foragers. The present relations are
similarly open to embellishment in simulation.
