[Received: 4 December 2019; Accepted: 14 January 2020]

Background: The contribution of glial cells to the pathophysiology of depression is an emerging research purpose. This study investigated the deficits in glial cells, specifically astrocytes in various brain regions, after the development of depression and then after voluntary running in depressed rats.

Materials and methods: Forty-five adult male Wistar rats aged 8–10 weeks were used in the study. A depression model was generated through a forced swimming programme; voluntary running was allowed on rat running wheels; and brain sections were taken from the hippocampus, dentate gyrus (DG), medial prefrontal cortex (mPFC) and cerebellar cortex. After immunostaining with specific antibodies immuno-stain, the astrocytes, oligodendroglia and microglial cells were counted, and certain indices relating astrocytes to other glial cells were calculated. Astrocytic morphology was studied, and the optical density (OD) of glial fibrillary acidic protein (GFAP) immuno-expression was measured in different groups.

Results: Compared to the control group, animals in the depression group exhibited significant decreases in the mean astrocyte count in all studied brain areas, significant decreases in GFAP OD values in all areas and significantly reduced values for all glial astrocyte indices in the hippocampus, DG and mPFC. Compared to the rats in the depression group, those in the depression/exercise group exhibited significantly elevated mean astrocyte and oligodendroglia counts in all studied areas, significantly elevated GFAP OD values in all studied areas, and non-significant differences in glial astrocyte indices in the hippocampus, mPFC and cerebellar cortex.

Conclusion: Astrocytes, rather than other glia, constitute a basis for the development and/or relief of depression. (Folia Morphol 2020; 79, 3: 419–428)

Key words: stress, dentate gyrus, hippocampus, cerebellum, frontal cortex, glial cells, voluntary running
**INTRODUCTION**

Depression is a neuropsychiatric ailment that has a major impact on socio-economic status. This disorder results from maladaptive neuroplastic processes in the cellular structures concerned with emotional processing, such as the prefrontal cortex (PFC), hippocampus and amygdala [18]. Neurotrophins and neuroplasticity are generally accepted to play an essential role in the pathophysiology of depression. However, the disturbance of synaptic plasticity due to glial cell pathology, particularly in the frontolimbic areas of the brain, is an emerging proposed mechanism that may substantially contribute to the pathophysiology of mood disorders [28].

Physical exercise can provide relief for depressed mood, but the underlying mechanisms remain uncertain. Studies designed to identify these mechanisms have discussed the changes in neurons with slight attention paid to changes in glial cells [11].

The term neuroglia describes all supporting non-neuronal cells in the central nervous system (CNS) that represent the homeostatic and defensive arm of nervous system [34]. Recently, a system of complex crosstalk between neurons and glia has been proposed, and the active role for glial cells in central homeostatic processes has been presented [29].

Astrocytes are a heterogeneous class of glial cells that preserve the neural microenvironment [7]. Their dynamic role in shaping synaptic function and their impact on behavioural expression are noteworthy [28]. Microglia are specific immune cells of the CNS that are highly dynamic, surveying the brain parenchyma and contributing to neuroprotection. During neurogenesis, microglia have a role in determining the ultimate patterns of the neural circuits important for behaviour and disease development [35]. These glia also have a critical role in the synaptic carving needed for adaptive brain function [37]. Oligodendroglia are myelin-forming cells that are generated continuously in healthy adult brains for regulation of the axonal function [20].

Experimental studies on the pathophysiology of depression usually focus on neuronal changes, with little attention has paid to changes in the neuroglia. This study aimed to consider changes in astrocytic counts and morphology in the hippocampus, dentate gyrus (DG), medial prefrontal cortex (mPFC) and cerebellar cortex of Wistar rats in an experimental depressive state and after voluntary running.

**MATERIALS AND METHODS**

This experimental study was conducted in the behaviour laboratory of the College of Medicine, Taibah University, Saudi Arabia. Cell counting and analysis were performed in the Department of Histology at the Bogomolets National Medical University, Ukraine. The animal handling was conducted in accordance with EC Directive 86/609/EEC for animal studies and the National Committee guidelines of Saudi Arabia.

**Experimental animals**

Fifty-five adult male Wistar rats aged 8–10 weeks and weighing 200–250 g were obtained from the animal house of the behaviour laboratory, housed in the laboratory for 7 days for acclimatisation, and observed for their movements and food consumption as markers of their ordinary behaviour. A 6-minute forced swimming test (FST) was performed for choosing rats with extreme test behaviour (less immobility duration and high distance moved) [1]. Selected animals (n = 45 rats) were housed in ventilated cages (5 animals/cage) with a standard chow diet and an adjusted laboratory environment (12/12-hour light/dark cycle, 22–24°C, 50–60% humidity) [11, 13].

Selected rats were randomly divided into three equal groups as follows:

- control group: rats were fed a standard chow diet for a period of 5 weeks;
- depression group: rats were subjected to the forced swimming programme for 2 weeks and then fed the standard chow diet for the following 3 weeks;
- depression/exercise group: rats were subjected to the forced swimming programme for 2 weeks and then allowed to voluntary wheel running for the following 3 weeks.

For all groups, the locomotor activities of the rats were assessed by the 6-minute FST before being sacrificed.

**Induction of depression**

Depression was induced by forced swimming inside an upright glass cylinder inclosing water (water height 45 cm and temperature at 23–25°C) for 15 min daily for 14 days. Every day after swimming, the rats were allowed to dry (32°C) for 15 min before being returned to their cages [11].

**Accessing voluntary running**

The rats were allowed to run voluntarily for 3 weeks in rat running wheels supplied with counters
Confirmation of the development and/or the relief of the depressive state

Two means were used to confirm the development or relief of a depressive state just before the rats were euthanised:

— the 6-minute FST, through automatic tracing via a software (Ethovision XT version 8.0, Noldus Information Technology, Wageningen, The Netherlands), was conducted to assess the locomotor behaviour of the rats in terms of a) immobility duration (in seconds) and b) the distance the rats moved (in centimetres) [26];

— quantification of serum corticosterone levels; in the morning, after anaesthetising the rats with ether, blood was collected from the retro-orbital veins and put into serum separation tubes for centrifugation. The sera were reserved in −80°C until the levels of corticosterone (ALPCO Diagnostics, Orangeburg, NY, USA) were measured using ELISA kits rendering the manufacturers’ instructions [2, 24].

Tissue preparation and quantification of glial cells

At the quantified time, the rats were sacrificed by cervical dislocation and perfused with formaldehyde (4%) in phosphate-buffered saline (PBS). The brains were removed, coronally sectioned, and fixed in buffered formalin for histological examination of the hippocampus, DG, mPFC and cerebellar cortex. Brain tissue thin sections (4–5 µm) were immunostained with polyclonal anti-rat antibodies (Dako Cytomation, USA) against glial fibrillary acidic protein (GFAP), myelin basic protein (MBP), and cluster of differentiation 68 (CD68). The staining procedure was performed as previously described [19] with an immunoperoxidase technique and a Bench-Mark instrument (Ventana Company, Oro Valley, Arizona, USA) briefly; The paraffin sections were deparaffinised, rehydrated, treated with 3% H₂O₂ for 5 min and washed with PBS for 15 min. The sections were blocked with 1.5% normal goat serum in PBS to control background staining and then incubated for 45 min at room temperature with the primary antibody. The sections were subsequently incubated with a second-stage biotinylated antibody at room temperature. After rinsing with PBS, the reaction products were visualised by immersing the sections in diaminobenzidine (DAB). Finally, the sections were counter-stained with haematoxylin, dehydrated and cover-slipped using Protex mounting media (DAB, Stock Stain box; Boster Biotechnology, Pleasanton, CA, USA) [16].

Sections were examined with a bright field automated microscope (Olympus BX 36 provided with a true-colour image analysis software package), photographs were captured from different brain sections to represent all strata of the hippocampus (alveus, oriens and radiatum and pyramidal), all layers of the DG (molecular, granular and polymorphic), all cell layers of the cerebellar cortex (molecular, Purkinje and granular) and all layers of the mPFC (molecular, outer granular, pyramidal, inner granular layer, ganglionic and multiform). The images were digitised by a DP27 digital video camera (2448 × 1920-pixel matrix) to identify different types of glial cells; GFAP + ve astroglia, MBP + ve oligodendroglia, and CD68 + ve microglia (Fig. 1) [19]. Cell counting was performed in the Department of Histology at the Bogomolets National Medical University, Ukraine. For each group, the stained astrocytes, oligodendroglia and microglia
were counted at 400× in 15 fields from the selected sections of the four brain regions.

The glial astrocyte indices

Three glial astrocyte indices (GAI) were calculated as a simple way to express the ratio of astrocytic count to the counts of other types of glia and to explore the impact of altered astrocytic numbers on glial structural homeostasis in the context of depression and also after voluntary running of depressed rats. They were expressed as follows: a) GAI1 (A/M) — number of astrocytes/the number microglia; b) GAI2 — number of astrocytes/number of oligodendroglia; and c) GAI3 (A/T) — number of astrocytes/total number of counted glial cells.

The measurement of optical densities of the GFAP

The optical densities (ODs) of the GFAP-stained sections were measured as described by Varghese et al. [32] in five illustrative non-overlapping fields (×400). The images were deconvoluted via the DAB vector, the brown DAB images were calibrated and the mean grey value. The OD was calculated using the equation: \[ OD = \log \left( \frac{\text{max intensity}}{\text{mean intensity}} \right) \], where max intensity = 250 and mean intensity = mean grey value.

Statistical analysis

Statistical analyses were done with the IBM SPSS statistical package (version 21). The data were stated as the mean ± standard error (SE). The means of the studied groups were compared using one-way ANOVA with the least significant different test for analysis of the locomotor parameters, corticosterone levels, glial cell counts and glial astrocyte indices. Statistical significance was set at p < 0.05.

RESULTS

The development and relief of the depressive state

The mean immobility duration recorded for the depression group was significantly higher than that for the control group. Further, the mean immobility duration recorded for the depression/exercise group was significantly lower than that for the depression group (Fig. 2).

The mean distance moved by the rats in the depression group was significantly lower than that moved by the rats in the control group. Also, the mean distance moved by the rats in the depression/exercise group was significantly higher than that recorded for the depression group (Fig. 2).

The mean serum corticosterone level was significantly higher in the depression group than in the control group. Furthermore, it was significantly lower in the depression/exercise group than in the depression group (Fig. 3).

Glial cell counts and glial astrocyte indices

The mean numbers and significance of the glial cells and glial astrocyte indices are presented in Table 1 and Table 2. Changes in the mean numbers of astrocytes in different regions for all groups are shown in Figure 4.

The mean number of astrocytes was significantly lower in the depression group than in the control group in all studied brain areas (hippocampus, DG,
mPFC and cerebellar cortex). However, no significant differences were detected for either oligodendroglia or microglia in the hippocampus, DG and mPFC between the depression group and the control group. Only oligodendroglia was significantly decreased in number in the cerebellar cortex.

Total glial cell counts were significantly lower in the depression group than in the control group in all studied brain areas except in the mPFC, where the decrease was not significant.

Excitingly, all glial astrocyte indices (GAI1, GAI2 and GAI3) were significantly lower in the depression groups than in the control group in all studied brain areas, except for a non-significant decrease in GAI1 and GAI3 in the cerebellar cortex.

Table 1. Means and significance of different glia cells’ numbers and the total glia cells’ counts in different groups in all examined brain areas

| Regions          | Variables    | Control (n = 15) | Depression (n = 15) | Depression/exercise (n = 15) | P value       |
|------------------|--------------|-----------------|--------------------|-----------------------------|---------------|
| Dentate gyrus    | Astrocytes   | 38.8 ± 5.6      | 11.8 ± 3.1         | 22.07 ± 1                   | P1 < 0.001*   |
|                  | Oligodendroglia | 11.47 ± 2.1    | 9.2 ± 0.8          | 98 ± 10.5                   | P1 = 0.314    |

|                  | Total glia cells | 39.9 ± 4.5    | 29.2 ± 3.7         | 60.8 ± 5.1                  | P1 = 0.098    |
| Hippocampus      | Astrocytes   | 30.6 ± 2.6     | 15.7 ± 2.8         | 22.8 ± 0.8                  | P1 < 0.001*   |
|                  | Oligodendroglia | 21.7 ± 2.6     | 18.5 ± 2.2         | 26.7 ± 0.8                  | P1 = 0.368    |
|                  | Microgliocytes | 10.9 ± 1.6     | 10.7 ± 1.0         | 7.7 ± 0.7                   | P1 = 0.918    |
|                  | Total glia cells | 63.2 ± 3.8    | 45 ± 4.1           | 57.3 ± 1.6                  | P1 < 0.001*   |
| Cerebellar cortex | Astrocytes   | 8 ± 1.2        | 4.33 ± 0.4         | 5.8 ± 0.3                   | P1 = 0.007*   |
|                  | Oligodendroglia | 238.3 ± 14     | 180 ± 10.3         | 353.3 ± 15.2                | P1 = 0.002*   |
|                  | Microgliocytes | 4.2 ± 0.4      | 4.3 ± 0.3          | 4.7 ± 0.3                   | P1 = 0.777    |
|                  | Total glia cells | 250.5 ± 14    | 188 ± 10.4         | 363.8 ± 15.2                | P1 = 0.002*   |

P1 significance of the depression group compared to the control group. Significance at p < 0.05; P2 significance of the depression/exercise group compared to the depression group. Significance at p < 0.05.
The mean numbers of astrocytes and oligoden-
droglia were significantly higher in the depression/
exercise group than in the depression group in all
studied brain areas (hippocampus, DG, mPFC and
cerebellar cortex). The mean number of microglia
was different in different regions (increased signifi-
cantly in the DG and mPFC, decreased significantly
in the hippocampus, and no significant increase in
the cerebellar cortex).

Total glial cell counts were significantly higher in
the depression/exercise group than in the depression
group in all studied brain areas except in the hip-
 pocampus, where the increase was not significant.
However, the glial astrocyte indices showed no
significant differences in the hippocampus, mPFC or
cerebellar cortex between the depression and depres-
sion exercise groups. In the DG, significant decreases
in GAI1 and GAI3 were detected, but these decreases
were accompanied by highly significant increases in
the numbers of microglia and oligodendroglia.

GFAP immunohistochemical study
An examination of the hippocampus, DG, mPFC
and cerebellar cortex in the control group revealed
star-shaped astrocytes with dense, distinct, dark cell
bodies and complex and “bushy”, densely packed
processes (Fig. 5). In depressed rats, astrocytes were

GAI1 (A/M) — number of astrocytes/number of microglia; GAI2 (A/O) — number of astrocytes/number of oligodendroglia; GAI3 (A/T) — number of astrocytes/total number of counted glial cells; P1 significance of the depression group compared to the control group; P2 significance of the depression/exercise group compared to the depression group. Significance at p < 0.05.
dispersed in all examined brain regions and displayed relatively indistinct cell bodies and distorted processes (Fig. 5). In the depression/exercise group, astrocytes in all regions appeared to regain their immune reactivity, exhibiting denser cell bodies and complex, denser process extensions than the depression group (Fig. 5).

Compared to the control group, depression caused a significant decrease in GFAP OD in the hippocampus (p = 0.013), DG (p < 0.001), mPFC (p < 0.001), and cerebellar cortex (p < 0.001) (Fig. 6).

Compared to the depression group, running caused a significant increase in GFAP OD in the hippocampus (p = 0.042), DG (p = 0.027), mPFC (p = 0.037), and cerebellar cortex (p = 0.026) (Fig. 6).

**DISCUSSION**

The development of depression and/or its relief were assessed both mechanically by evaluating locomotor behaviours (through FST) or biochemically by evaluating the serum corticosterone levels in all groups. The significant decrease of the distance moved, the significant increase in the immobility duration and the increased corticosterone levels after the forced swimming protocol confirmed the development of depression. Similarly, a significant increase in the mean distance moved, a significant decrease in the mean immobility duration and a significant decrease in serum cortisol levels occurred after a voluntary running protocol confirmed the relief of depressive behaviour [3, 5].
Depression was primarily proposed to develop due to increased levels of corticosteroids [21]; later, neurotrophic factors and disordered neuroplastic processes in the frontal cortex and limbic system were proposed as underlying mechanisms [6, 11]. Based upon the emerging concept that glial cells, specifically astrocytes, are critical factors affecting brain plasticity [28], this study evaluated the changes in glial cells (specifically astrocytes) in the hippocampus, DG, mPFC, and cerebellar cortex as a key mechanism triggering the pathophysiology of depression.

The significant decrease in the mean total glial cell counts in the hippocampus, DG, and cerebellar cortex reflected the contribution of glial cells to the pathophysiology of depression. This finding was consistent with a recorded reduction in glia during depression that was proven to precede the decreased neuronal density, which appears to occur later after longer periods of depression [23].

The significant decrease in the mean number of astrocytes, along with non-significant differences in the mean count of oligodendroglia or microglia, in most of the examined brain areas, can reflect the major role of astrocytes in the pathology of depression. Additionally, the decreased glial astrocyte indices can outline the role of astrocytes over other glia in the development of depression. These findings are consistent with the reported decreased density of astrocytes associated with synaptic dysfunction in the frontal and limbic regions for cognition [30]. The improved behaviour after voluntary running, are in line with the suggested physical activity-induced plasticity of astrocytes and enhanced synaptic markers in the brain regions for cognition [30]. The improved behaviour might be due to the trophic support and regulation of neuronal blood flow by astrocytes, which influence neuronal function and synaptic growth [12, 22].

Practising voluntary running by depressed rats improved the depressive locomotor behaviour and produced a significant increase in the total glial cell counts and significant increase of the OD of the GFAP-stained sections in the brain areas. This can indicate the concomitant improving effect on glial cell counts with the improvement of the depressive behaviour after voluntary running. This was consistent with the observed alleviation of depression-like symptoms and the enhancement of synaptic, and glial measures in several brain regions upon exercise [34].

The increased number of astrocytes in the mPFC, hippocampus and DG, along with improved depressive behaviour after voluntary running, are in line with the suggested physical activity-induced plasticity of astrocytes and enhanced synaptic markers in the brain regions for cognition [30]. The improved behaviour might be due to the trophic support and regulation of neuronal blood flow by astrocytes, which influence neuronal function and synaptic growth [12, 22].

Also, the improved astrocytic counts and increased GFAP expression after running are consistent with the suggested important glioprotective effects and...
the prevention of stress-induced decreases in GFAP expression in the hippocampus after treatment with antidepressants [8].

Notably, although astrocyte counts increased in all brain areas after running, there were non-significant increases in the proposed glial astrocyte indices in the hippocampus, mPFC and cerebellar cortex. This finding showed that voluntary running increased the astrocyte count to levels capable of preserving neurons and oligodendroglia, limiting brain tissue degeneration and preserving the function without reaching the levels of astrogliosis, which can lead to neurotoxicity, potential neural dysfunction and the development of neurodegeneration [4]. The significant decreases in GAI1 and GAI3 in the DG can be explained by the specifically significant increase in microglia to this region, which might be enhanced to help shaping the final patterns of neural connections during neurogenesis [10, 35].

CONCLUSION

These collected data provide evidence for a prominent role of glial cells in the pathology of depression. Furthermore, the study presents significant changes in astrocyte count and/or morphology in the hippocampus, DG, mPFC and cerebellar cortex in depression. The study reveals the noteworthy ability of voluntary running to reverse the effects of depression on the abundance of astrocytes and on their specific marker GFAP in the brain regions associated with depression. Additionally, this work provides evidence that both astrocytes and oligodendroglia are implicated in the mitigating effect of voluntary running on depression in the hippocampus, DG, mPFC and cerebellar cortex.

Acknowledgement

The authors express thanks for the technicians of the behavioural lab, College of Medicine, Taibah University, who helped us throughout conduction of the experiment.
