Abstract

Massive splenomegaly is related to several challenges for the surgeon and higher intraoperative complications, due to the limited working space, the difficulties in spleen manoeuvre and the increase in bleeding. A splenic artery embolization can be performed before the surgery, in order to decrease both the size of the spleen and the risk of bleeding.

Here, we report the case of a 56-year-old man diagnosed with massive splenomegaly, secondary to a marginal splenic lymphoma, which had a maximum diameter of 54 cm. The surgery was recommended because of progressive anemia requiring monthly transfusion of red blood cells, thrombocytopenia, abdominal pain and constitutional symptoms. Clinical exam showed a massive splenomegaly that overtook the midline and reached the hypogastric region. Preoperative computed tomography (CT), performed 6 months before the surgery, confirmed the enlarged spleen with a diameter of 54 x 28 x 14 cm associated with moderate ascites, bilateral pleural effusion and enlarged retroperitoneal lymph nodes (Fig. 1). Bone marrow aspiration demonstrated a low-grade B lymphoproliferative disorder, CD5+, CD19+ and CD20+.

A complete splenic artery embolization (SAE) was performed three hours prior to surgery. The catheter tip, inserted through the femoral artery, was advanced to the splenic artery distal to the gastroepiploic artery, and Polyvinil Alcohol Foam of 700 -100 microns, coils IMWCE-35-15-10 COOK and an Amplazter Vascular Plug 4 were injected inside the vessel (Fig 2A). A posterior angiogram was performed to verify the complete occlusion of the splenic artery (Fig 2B). The patient did not complain of pain, and an evident decrease in spleen size was observed on physical examination.

Abbreviations

MS: massive splenomegaly; SAE: splenic artery embolization; CT: computed tomography

Introduction

Massive splenomegaly (MS) has been defined as a spleen >17-20 cm in length or >1000-1500 g in weight [1, 2]. Splenectomy for MS presents several challenges for the surgeon; therefore, in order to reduce intraoperative complications, decreasing both the size of the spleen and the risk of bleeding, a splenic artery embolization (SAE) can be performed before the surgery.

Here, we report a case of MS with a weight of 6,300 g and a diameter of 48 x 24 x 11 cm submitted to splenectomy combined with SAE.

Case report

A 56-year-old man with marginal splenic lymphoma was recommended for splenectomy because of progressive anaemia (4.5 g/dL), requiring monthly transfusion of red blood cells, leucocytosis (107,000/mm3), thrombocytopenia (63,000 / mm³), abdominal pain and constitutional symptoms. Clinical exam showed a massive splenomegaly that overtook the midline and reached the hypogastric region. Preoperative computed tomography (CT), performed 6 months before the surgery, confirmed the enlarged spleen with a diameter of 54 x 28 x 14 cm associated with moderate ascites, bilateral pleural effusion and enlarged retroperitoneal lymph nodes (Fig. 1). Bone marrow aspiration demonstrated a low-grade B lymphoproliferative disorder, CD5+, CD19+ and CD20+. A complete splenic artery embolization (SAE) was performed three hours prior to surgery. The catheter tip, inserted through the femoral artery, was advanced to the splenic artery distal to the gastroepiploic artery, and Polyvinil Alcohol Foam of 700 -100 microns, coils IMWCE-35-15-10 COOK and an Amplazter Vascular Plug 4 were injected inside the vessel (Fig 2A). A posterior angiogram was performed to verify the complete occlusion of the splenic artery (Fig 2B). The patient did not complain of pain, and an evident decrease in spleen size was observed on physical examination.

Figure 1: Computed tomography showing a coronal section of the giant abdominal mass reaching the pelvis.
(Fig. 3). The patient was placed in the left semilateral position and an open splenectomy through a left Makuuchi incision was performed without intraoperative complications. Intraoperative blood loss was 300 cc, the operative time was 180 minutes. The resected spleen weighed 6,300 g and had a diameter of 48 x 24 x 11 cm. The pathologic report described a low-grade B lymphoproliferative disorder, CD5+, CD20+ and Bcl-2+, compatible with marginal splenic lymphoma stage IVB Ann Arbor. The post-operative course was characterized by a post-operative ileus. The total length of hospital stay was 16 days.

**Discussion**

Laparoscopic splenectomy, since its first report in 1991 [3], has become the gold standard for normal-sized spleen, although massive splenomegaly removal is associated with higher intraoperative complications compared to normal-size splenectomy. The main challenges for the surgeon are represented by the limited working space, the difficulties in spleen manoeuvre and the increase in bleeding risk, because of its peculiar vascularity. Targarona et al. [4], in their series of 186 patients submitted to splenectomy, reported that all spleen over 3.2 kg required conversion, although later reports have shown low conversion rate even in spleen > 3 kg [5]. For this reason, an open approach can be reasonably preferred in selected patients like ours, which represents one of the biggest spleen resected after SAE.

The SAE prior to surgery, firstly described by Maddison in 1973 [6], represents a reliable procedure as it can decrease spleen size, intraoperative bleeding and operative time. As shown by Iwase et al. [7], a decrease of 60% in spleen volume can be observed after SAE. In our case, a significant reduction in the size of the spleen was observed after the embolization, and this achievement considerably simplified the surgery. Naoum et al. [8] reported a significant reduction in intraoperative blood from 240 mL to 25 mL (p < 0.003) when SAE was performed. Even though it is generally recommended realizing a SAE for spleen > 20 cm, a consensus about the indication of the procedure and the timing does not exist.

Complications related to SAE have been described. Post-infarction syndrome, as well as pancreatitis or pancreatic necrosis, and acute gastritis ulcers may occur [9]. Post infarction syndrome is characterized by fever and left flank pain. It has been recommended to perform the SAE the day before or on the same day as the surgery, but probably the best strategy to decrease the likelihood of uncontrolled pain is to carry out the procedure on the day of the splenectomy or combine both procedures in an intraoperative approach.

**Conclusion**

SAE represents a safe and feasible technique in cases of massive splenomegaly, in order to reduce the spleen size and the risk of bleeding. The laparoscopic approach should be recommended, however, in selected cases, an open approach represents a valid alternative to the extent of reducing the chances of intraoperative complications.
