In this paper, we shall perform a detailed analysis of the Exact Holographic Mapping first introduced in arXiv:1309.6282, which was proposed as an explicit example of holographic duality between quantum many-body systems and gravitational theories. We obtain analytic results for free fermion systems that not only confirm previous numerical results, but also elucidate the exact relationships between the various physical properties of the bulk and boundary systems. Our analytic results allow us to study the asymptotic properties that are difficult to probe numerically, such as the near horizon regime of the black hole geometry. We shall also explore a few interesting but hitherto unexplored bulk geometries, such as that corresponding to a boundary critical fermion with nontrivial dynamic critical exponent. Our analytic framework also allows us to study the holographic mapping of some of these boundary theories in dimensions 2+1 or higher.

I. INTRODUCTION

In the recent years, holographic duality, also known as the Anti-de-Sitter space/Conformal Field Theory (AdS/CFT) correspondence\(^1\)\(^-\)\(^3\), has attracted tremendous research interest in both high energy and condensed matter physics. This correspondence is defined as a duality between a \(D + 1\)-dimensional field theory on a fixed background geometry and a \(D + 2\)-dimensional quantum gravity theory. The best understood example of holographic duality is the correspondence between \(4\)-dimensional super-Yang-Mills theory and \(5\)-dimensional supergravity. There, the large-\(N\) limit of the super-Yang-Mills theory corresponds to the classical limit of the dual gravity theory, which provides a helpful description of strongly coupled gauge theories. What makes holographic duality particularly interesting is its generality. When the boundary theory is not a conformal field theory, a dual theory with a different space-time geometry may still be well-defined.\(^4\)

Physically, holographic duality can be understood as a generalization of the renormalization group (RG) flow of the boundary theory\(^5\)\(^-\)\(^7\), where bulk gravitational dynamics generalize the RG flow equations and the emergent dimension perpendicular to the boundary has the physical interpretation of energy scale\(^8\)\(^,\)\(^9\). Indeed, holographic duality has been applied to condensed matter physics as a new tool to characterize strongly correlated systems\(^10\)\(^-\)\(^13\).

More recently, holographic duality has been proposed to be related to another approach developed in condensed matter physics, namely tensor networks\(^14\)\(^-\)\(^22\). In its most general form, tensor networks refer to a description of many-body wavefunctions and operators (i.e. linear maps) by contracting tensors defined on vertices of a graph.\(^23\)\(^-\)\(^28\) More specifically, the tensor network state proposed to be related to holographic duality is the multiscale entanglement renormalization ansatz (MERA)\(^26\)\(^,\)\(^27\), which is defined on a graph with hyperbolic structure, with external indices (corresponding to the physical degrees of freedom) at the boundary and internal indices contracted in the bulk. An important feature of states described by tensor networks is that the entanglement entropy of a given region is bounded by the number of links between the region and its complement. This property motivated its relation to holographic duality\(^14\), where the entanglement entropy of a given region is determined by the area of the minimal surface bounding it, in accordance to the Ryu-Takayanagi formula\(^29\).

There are many open questions in the proposed tensor network interpretation of the holographic duality. One important question is how to describe space-time geometry rather than spatial geometry. Another (related) question is how to understand excitations (quantum fields) living in the bulk. Motivated by these questions, one of us\(^30\) proposed a tensor network which defines not a many-body state but a unitary mapping between the boundary and bulk systems, known as the exact holographic mapping EHM. The EHM is a tensor network very similar to MERA, except that it is a one-to-one unitary mapping between boundary and bulk degrees of freedom. Each boundary state \(\langle \psi \rangle\) is mapped to a bulk state \(|\tilde{\psi}\rangle = M|\psi\rangle\), and each boundary operator \(O\) is mapped to a bulk operator \(\tilde{O} = MOM^{-1}\). Physically, the EHM is a “lossless” version of real space renormalization group. Denoting a site in the bulk as \(x\), a local operator at that site \(\tilde{O}_x\) is dual to a generically nonlocal operator on the boundary \(O_x = M^{-1}\tilde{O}_x M\). Different bulk sites \(x\) correspond to operators \(O_x\) on the boundary with different energy scales and different center-of-mass locations of their support. Once a mapping \(M\) is chosen, bulk correlation functions can in principle be calculated. Motivated by the general principle of relativity, the bulk geometry was proposed to be determined by the bulk correlation functions. More specifically, the distance between two points was proposed to depend logarithmically on the connected two point correlation functions. Compared to previous tensor network proposals, the EHM is different in two aspects: i) The bulk geometry is not determined by the structure of the tensor network but by the correlation structure of the bulk state; ii) The bulk geometry can be studied in both the spatial and temporal direction by studying the bulk correlation functions. In Ref. 30, an explicit choice of the mapping \(M\) for \((1 + 1)\)-dim lattice fermions was proposed, and the consequent dual geometries corresponding to different boundary states were studied. They included the ground state of massless and massive fermions, the nonzero temperature thermal ensemble of massless fermions, and a thermal double state which is a purification of the thermal ensemble. Dynamics after a quantum quench was also studied in the thermal double system, motivated by a comparison with geometrical properties of a two-sided black hole spacetime\(^18\).

The results in Ref. 30 for the abovementioned free fermion systems were obtained numerically. This limits the extent of analysis, due especially to the exponential growth of boundary system size. To have a well-defined bulk geometry with \(n\) layers in the emergent direction of the bulk perpendicular to the boundary, the boundary system has to have \(2^n\) sites. In this paper, we shall obtain analytic results on the free fermion EHM, which will enable us to rigorously determine asymptotic properties of the dual geometry, and also to discuss more general boundary systems. For instance, the existence of a black hole horizon in the geometry dual to a nonzero temperature state at the boundary can be studied more explicitly from the asymptotic infrared behavior of correlation functions in both spatial and temporal directions. In addition to reproducing the results of Ref. 30 analytically, we shall also explore a few other interesting emergent bulk geometries, such as that corresponding to a critical
fermion with nontrivial dynamic critical exponent. Our analytic framework also allows us to generalize the EHM to boundary theories with dimension 2 + 1 or higher\(^3\), in which case the analytic approach is more essential due to the increasing difficulty of numerical calculations\(^3\). An added advantage of an analytic approach is that it allows one to identify properties of the bulk geometry that are insensitive to details of the choice of the mapping which thus reflects intrinsic properties of the boundary state.

This paper will be structured as follows. In Section II, we first review the EHM construction by describing its general principles and the definition of bulk geometry. These ideas will be elaborated in Section III for free lattice fermions, where an explicit Haar wavelet representation of the EHM will be presented. In Section IV, we provide detailed descriptions of the asymptotic correlator behavior and corresponding bulk geometries for the prototypical 1 + 1-dim Dirac Model at various combinations of zero and nonzero temperature and mass. These developments will be further extended to higher dimensions and generic energy dispersions in Section V, where we discuss the emergence of interesting geometries like anisotropic black hole horizons with nontrivial topology.

II. REVIEW OF THE EXACT HOLOGRAPHIC MAPPING

In this section, we shall review the motivation and construction of the EHM proposed in Ref. 30 in a formalism that will be helpful for the later part of this paper. We will also include some new insights that are not discussed in the original proposal. The EHM approach is defined by the following two principles:

1. The bulk theory and boundary theory are defined in the same Hilbert space. The bulk local operators are determined by a unitary mapping acting on the boundary local operators.

2. The bulk geometry is determined by physical correlation functions. More specifically, the distance between two space-time points \(x, y\) in the bulk is determined by the connected correlation functions between the two points.

Although the abovementioned unitary transformation can be very generic in principle, the types of transformations that are relevant for holographic duality are those which are physically analogous to the renormalization group\(^33,34\). The bulk operators at different locations should represent boundary degrees of freedom with different energy scales. The key difference from the conventional RG approach is that the high energy degrees of freedom are spatially separated from low energy ones, instead of being integrated out. This enables us to concretely answer many new questions, such as how the high and low energy degrees of freedom (DOFs) are entangled/correlated. In the following, we will elaborate on the two abovementioned principles in the context of free fermion systems, and discuss the transformation of free fermion Hamiltonians under EHM.

A. General construction of EHM

The Exact Holographic Mapping is a unitary transformation defined by a tensor network or, equivalently, a quantum circuit consisting of local unitary operators. As proposed in Ref. 30, a simple construction of the EHM is given by a tree-shaped tensor network depicted in Fig. 1, where bulk (red) sites at the same level belong to the same ‘layer’. To construct it, we first take a \(D + 1\)-dimensional boundary system to be the zeroth bulk layer with \(L^D = 2^{ND}\) sites. To construct the first bulk layer, one performs a unitary transform \(U\) on every set of \(2^D\) adjacent sites such that the UV and IR (high and low momentum, assume a monotonic energy dispersion) degrees of freedom are separated out. For \(D = 1\), this can be written as

\[
U_{12}|\psi_1\psi_2\rangle = \sum_{\alpha, \beta} U_{\psi_1\psi_2|\alpha\beta} |\alpha\rangle_{1R}|\beta\rangle_{UV}
\]  

where \(U_{12}\) only acts on states \(\psi_1, \psi_2\) on sites 1 and 2 respectively, and \(|\alpha\rangle\) and \(|\beta\rangle\) capture the lower and lower momentum degrees of freedom respectively, also The full transformation on the zeroth layer is given by

\[
U = U_{12} \otimes U_{34} \otimes \ldots \otimes U_{2N-1,2N},
\]

which is a unitary transform on the Hilbert space of the whole layer. For \(D > 1\) dimensions, \(U\) will be given by the direct product of \(D\) copies of the expression in Eq. 2.

We construct the first bulk layer from the component \(|\beta\rangle = |\beta\rangle_{UV}\) in Eq. 1, which has the UV half of the degrees of freedom in the original layer. The other lower energy half \(|\alpha\rangle\), which we shall call the auxiliary sites in deference to Ref. 30, are fed into another copy of \(U\) with half the number of sites. This process is iterated for \(N\) times, each time producing a new layer in the bulk that has \(1/2^D\) the number of sites as the preceding layer, until only one site is left. The resultant (bulk) tree\(^35\) is unitary equivalent to the original (boundary) system, and is illustrated in Fig. 1.
B. Emergent bulk geometry through boundary correlators

The key motivation behind the EHM approach is to uncover the relationship between space-time geometry and the quantum entanglement properties of a quantum many-body system. The unitary mapping defined by the tensor network defines a new direct-product decomposition of the Hilbert space, and is chosen to make physical correlation functions more local in this new basis. To be more precise, we assume that the two-point connected correlation functions in the bulk always decay exponentially, according with the geodesic distance of certain emergent geometry:

\[ C_{(x_1,t_1),(x_2,t_2)} \equiv \langle O_{x_1}(t_1)O_{x_2}(t_2) \rangle - \langle O_{x_1}(t_1) \rangle \langle O_{x_2}(t_2) \rangle \propto \exp \left( -d_{(x_1,t_1),(x_2,t_2)} / \xi \right) \]

This assumption can conversely be used as a definition of the distance:\n
\[ d_{(x_1,t_1),(x_2,t_2)} = -\xi \log \frac{C_{(x_1,t_1),(x_2,t_2)}}{C_0} \]

where \( C_0 \) and \( \xi \) control the overall offset and scaling respectively. \( \xi \) can be physically interpreted as the inverse mass of the emergent bulk theory, which may depend slightly on how we perform the EHM. The logarithmic dependence is physically motivated by the observation that for a massive system, \( d_{(x_1,t_1),(x_2,t_2)} \) should recover the Euclidean distance in the original system.

In this work, we shall for simplicity focus on systems that are translationally-invariant in space and time, and study only correlators with purely space or time intervals, i.e. \( \Delta t = t_2 - t_1 = 0 \) or \( \Delta x = x_2 - x_1 = 0 \).

In the former case with purely spatial interval, all two-point connected correlators are bounded above by the mutual information:

\[ I_{xy} = S_x + S_y - S_{xy} \]
in Appendix G1 that the Mutual Information is approximately

\[ I_{xy} = S_x + S_y - S_{xy} \]

\[ \approx \frac{1}{2} \text{Tr} \left[ C_{x-y} \frac{1}{C_y} (I - C_y) C_{y-x} + (x \leftrightarrow y) \right] \]

\[ \sim \text{Tr}[C_{y-x} C_{y-x}] \] (9)

where \( C_x, C_y \) are the single-particle onsite correlators, and \( C_{x-y} \) is the single-particle propagator between the two different sites \( x \) and \( y \). This result is completely general, and implies that

\[ d_{\Delta x} = -\xi_{\Delta x} \log \frac{I_{xy}}{I_0} \sim 2\xi_{\Delta x} \log \text{Tr} C_{y-x} \] (10)

in the limit of large spatial separation \(|x - y|\). That \( C_x, C_y \) drops out is hardly surprising, as they each depend only on one site, and has no knowledge about their separation. Indeed, most of the information transfer in the asymptotic limit is dominated by the single-particle propagator.

We also define the temporal distance via

\[ d_\tau = -\xi_\tau \log \frac{\text{Tr} C(\tau)}{\text{Tr} C(0)} \] (11)

where a trace of the fermion states have been taken. This is the simplest possible basis-independent combination of the components of \( C(\tau) \).

In the next subsections, we will introduce prototypical fermionic models as the boundary systems in 1+1 and higher dimensions, and show how their corresponding bulk distances and hence geometries can be computed via suitable holographic unitary mappings.

A. EHM for (1+1)-dimensional lattice Dirac fermions

The (1+1)-dimensional lattice Dirac model is among the simplest models with a single critical point. In this subsection, we will summarize the explicit construction of the EHM for this system. Its simplicity allows us to study its multitude of entanglement and geometric properties analytically with minimal complication.

The (1+1)-dim Dirac hamiltonian is a 2-band hamiltonian given by

\[ H_{\text{Dirac}}(k) = v_F \sin k \sigma_1 + M(m + 1 - \cos k) \sigma_2 \] (12)

where \( \sigma_1, \sigma_2 \) are the Pauli matrices and \( v_F \), the Fermi velocity, controls the overall scale of the dispersion. When \( m = 0 \) or \( \pm 2 \), its gap closes at \( k = 0 \) and it becomes critical with two crossing bands with linear dispersion.

To explore or "zoom into" the low energy (IR) degrees of freedom (DOFs), we utilize a unitary transform that maps states \( |\psi_1^s\rangle, |\psi_2^s\rangle \) on neighboring sites into symmetric (low energy) and antisymmetric (high energy) linear combinations \( \frac{1}{\sqrt{2}} (|\psi_1^s\rangle \pm |\psi_2^s\rangle) \). Note that the unitary transform does not rotate the spin labels \( s_1, s_2 \), which we shall suppress in the following. In matrix form, the unitary transform is written as

\[ U_{12} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \] (13)

The symmetric combination has a Fourier peak at \( k = 0 \), which is exactly the gapless point of the critical \((m = 0)\) Dirac model. The discerning reader will notice that \( U_{12} \) is nothing other than the defining expression for the Haar wavelet. Indeed, the construction of the EHM basis is mathematically identical to performing a wavelet decomposition\(^{40-42}\). A systematic study of all possible wavelet descriptions of the EHM will be deferred to future work, since for this work we will be primarily concerned about the behavior of the bulk geometries due to qualitatively different boundary systems, not the details of the wavelet mapping. The transform given by Eq. 13 possess the virtue of simplicity and, most importantly, fixes the archetypal Dirac Hamiltonian, a property we shall prove in the next subsection.

More insight into the EHM can be gleaned in momentum space, where one can directly see how the Hilbert space is decomposed into layers with different momentum spectral distributions. Fourier transforming the action of Eq. 13 on the single particle states, we obtain \( |\alpha_k\rangle = \sum_{2k} C(e^{ik}) |\psi_{2k}\rangle \) and \( |\beta_k\rangle = \sum_{2k} D(e^{ik}) |\psi_{2k}\rangle \) for the auxiliary and bulk states respectively, where \( |\psi_k\rangle \) is the periodic part of the Bloch state and

\[ C(e^{ik}) = \frac{1}{\sqrt{2}} (1 + e^{ik}) \], \hspace{1cm} (14)

\[ D(e^{ik}) = \frac{1}{\sqrt{2}} (1 - e^{ik}) \] (15)

We shall call \( C, D \) the IR and UV (low energy and high energy) projectors. Physically, they represent the spectral weight projected to the auxiliary and bulk DOFs at each iteration. Through these iterations, we obtain successive basis projectors for each bulk layer that are increasingly sharply peaked in the IR. To understand this, note that the basis projector of the \( n^{th} \) layer \( W_n(z) = W_n(e^{ik}) \) is obtained from \( n - 1 \) consecutive IR outputs \( |\alpha\rangle \) and one final UV output \( |\beta\rangle \). Hence the first bulk layer should contain the DOFs projected from the UV projector \( D(e^{ik}) \), while the second layer should contain an IR projector \( C(e^{ik}) \) followed by an UV projector \( D(e^{2ik}) \) that peaks at half the momentum. This reasoning generalizes to all the \( N \) layers, so the normalized projector for the \( n^{th} \) layer is given in momentum space by (writing \( z = e^{ik} \))
$W_n(z) = \frac{1}{\sqrt{2\pi}} D \left( z^{2^{-n}} \right) \prod_{j=1}^{n-1} C \left( z^{2^{j-1}} \right)$

$= \frac{1}{\sqrt{2\pi}} \frac{1 - z^{2^n}}{\sqrt{2^n}} \prod_{j=1}^{n-1} \left( 1 + z^{2^{j-1}} \right)$

$= \frac{1}{\sqrt{2\pi}} \frac{1}{\sqrt{2^n}} \left( 1 - z^{2^n-1} \right)^2.$

(16)

$W_n(e^{ik})$ contains a series of peaks interspersed by valleys at $e^{i2\pi^{-n}k} = 1$. The dominant peaks occur at $k = \pm k_0 \approx \frac{\pi}{2^n}$ where the denominator is most singular, as shown in Fig. 2, and has magnitude $|W_n(e^{ik_0})| = \sqrt{\frac{2^n+1}{\pi^2}}$. This means that as $n$ increases, the spectral weight of the $n^{th}$ bulk layer exponentially approach the IR point at $k = 0$. One can further show that the $W_n$'s form a complete orthonormal basis, i.e. $\int_{-\pi}^{\pi} W_n^*(e^{ik})W_{n'}(e^{ik})dk = \int_{|z|=1} W_n^*(z^{-1})W_{n'}(z)\frac{dz}{2\pi} = \delta_{nn'}$, where the conjugation symbol in $W^*$ denotes that only the coefficients of $W(z)$, not the argument $z$, are complex conjugated. Indeed, that the $W_n$'s are orthonormal with peaks $k_0 \sim 2^{-n}$ is testimony to the fact that the EHM is a unitary mapping that separates the momentum (or energy) scale.

Note that the auxiliary projector, i.e. projection to auxiliary sites with the IR (low energy) half of the DOF, is just the orthogonal complement of $W_n(z)$ in Eq. 16: It is given by $\frac{1}{\sqrt{2\pi}} \prod_{j=1}^{n-1} C(z^{2^{j-1}})$, comprising IR projectors $C(z)$ only.

From Fig. 2, we see that the bulk basis become more effective in separating different momentum (and hence energy) scales as $n$ increases, since they become more sharply peaked. This property is due to the recursive nature of the definition Eq. 16, which also implies that physical quantities, i.e. correlators must scale universally with $n$ in the IR limit. However, departures from universal scaling may occur at small $n$ (UV regime) due to the non-universal high energy characteristics of the boundary system.

Note that the abovementioned unitary EHM transform successively "zooms into" the low energy DOFs of any model with a critical point at $k = 0$, and not just that of the Dirac model.

Having defined the mapping explicitly, we now write down the explicit expression of the bulk correlators. Previously, we have seen how the bulk distance can be expressed in terms of the bulk correlators $C_x, C_{x-y}$ and $C(\tau)$, which are the onsite, spatial and temporal propagators respectively. In the free fermion system discussed here, the bulk correlators are determined by the boundary two-point correlators

$G_q(\tau) = e^{i(H(\mathbf{q})-\mu)}(1 + e^{i\beta(H(\mathbf{q})-\mu)})^{-1}$

(17)

where $H(\mathbf{q})$ is the boundary single particle Hamiltonian matrix, $\mu$ the chemical potential and $T = 1/\beta$ the temperature. Explicit expressions for $G_q(\tau)$ as well as their resultant mutual information $I$ are derived in Appendix A For cases with particle-hole symmetry, which includes the Dirac model. In the zero temperature limit, $G_q(0)$ reduces to a projector onto the occupied bands below the chemical potential. In the extremely high temperature limit, it becomes nearly the identity operator, which just means that almost every state is equally accessible. In the reminder of the draft, we will always focus on imaginary time correlator unless otherwise stated, since it is still unclear how to define time-direction distance from the rapidly oscillating real time correlators (as discussed further in Appendix H).

The bulk correlators are most easily expressed as a sum in momentum space, since we have already found projections to the various bulk layers in terms of the spectral weight. Taking the thermodynamic limit where the boundary system is infinitely large, i.e. $N \to \infty$, the sum over momenta can be replaced with an integral. The bulk correlator between two bulk points $(x_1, n_1, 0)$ and $(x_2, n_2, \tau)$ is given by

$C(n_1, n_2, \Delta(2^n x), \tau)$

$= \sum_q W_{n_1}^*(e^{iq})W_{n_2}(e^{iq})e^{i\beta\Delta(2^n x)}G_q(\tau)$

(18)

where $\Delta(2^n x) = 2^{n_2}x_2 - 2^{n_1}x_1$ is the bulk angular interval and $G_q(\tau)$ is the (matrix-valued) $(1+1)$-dim boundary correlator. The indices $n_1, n_2$ specify the coordinates ('layers') in the emergent 'radial' momentum-scale direction in the bulk. There is no translational symmetry in this momentum(or energy)-scale direction, unlike the original spatial and temporal directions.

We see that $C(n_1, n_2, \Delta x, \tau)$ is just a Fourier transform of the boundary correlator $G_q$ weighted by the spectral
contributions $W_n^x, W_n^y$ of the respective bulk layers. One important observation is that the spatial coordinate in the exponential factor is $\Delta(2^n x)$, not $\Delta x$. This is because the correlation comes from the holographic projection of the bulk sites onto the boundary, which depends on the angle subtended by the bulk displacement: In the simplest case of a circular boundary, the angle subtended by the bulk displacement: In the simplest case of a circular boundary, the angle subtended by the bulk displacement: In the simplest case of a circular boundary, the angle subtended by the bulk displacement: 

\[
\Delta x = \frac{\pi}{2(D+1)} = \frac{\pi}{2} (2^n \Delta x).
\]

The bulk correlator still possesses translation invariance, but due to the rescaling of angular distance is also required for the orthogonality of the basis $\{W_n(q)e^{i2^n q x}\}$, $x = 1, 2, ..., L/2$.

### B. Transformation of the Hamiltonian under the EHM and its fixed points

The EHM is an exact version of renormalization group (RG) transformation. In each step, the DOFs of the system are split into high energy (UV) and low energy (IR) parts, with the procedure iterated on the low energy part. If we write the Hamiltonian in the new basis after an EHM step and ignore the coupling between the IR and UV degrees of freedom, we can write down a "low energy effective Hamiltonian" of the IR states. This resembles the renormalization group flow of the effective Hamiltonian in ordinary RG. For a given choice of the EHM tensor network, there are certain boundary systems for which the IR Hamiltonian is at an RG fixed point. In the following, we will show that the massless Dirac Hamiltonians are RG fixed points of the EHM transformation we defined earlier.

We start by writing down the effective IR Hamiltonian in the momentum basis. In $D = 1$ spatial dimensions, the EHM for each iteration is given by the change of basis in Eqs. 14 and 15, so the single particle Hamiltonian matrix $h_n^i$ of the $n^{th}$ layer is transformed according to

\[
h_{n+1}(e^{i k/2}) = \left[ V^t \begin{pmatrix} h_n(e^{i k/2}) & 0 \\ 0 & h_n(e^{i (k/2+\pi)}) \end{pmatrix} V \right]_{11}
\]

with the two components of the matrix representing the IR and UV DOFs. Here $V(w) = \sqrt{2} \begin{pmatrix} C(w) & D(w) \\ C(-w) & D(-w) \end{pmatrix} = \frac{1}{2} \begin{pmatrix} 1 + w & 1 - w \\ 1 - w & 1 + w \end{pmatrix}$, where $w = e^{i k/2}$. To obtain the Hamiltonian at the $(n+1)^{th}$ layer, one projects onto the upper left or IR component of the RHS. With $D > 1$ spatial dimensions, $V$ will be given by $V(w_1) \otimes ... \otimes V(w_n)$. If the Hamiltonian is to remain invariant under the RG, the 11 (IR) component in Eq. 19 gives $2h_n^{n+1}(w) = 2\lambda h_n^1(w^2)$ or, in detail:

\[
2\lambda h_n^1(w^2) = h_n^i(w)C(w)C^*(-w) + h_n^i(-w)C(-w)C^*(-w) = (h_n^i(w) + h_n^i(-w)) + \frac{w + w^{-1}}{2}(h_n^i(w) - h_n^i(-w))
\]

(20)

where $\lambda$ is a constant scale factor for each EHM step. Upon setting $w = 1$, we obtain

\[
\lambda h(1) = h(1)
\]

which implies that $\lambda = 1$ unless $h(1) = 0$, i.e. that the rescaling $\lambda$ for each step can be nontrivial ($\lambda \neq 1$) only if the hamiltonian is gapless but at the IR point $k = 0$ or $w = 1$. In other words, only gapless hamiltonians can have nontrivial scale invariance, as is expected. This has very important implications in spatial dimensions $D > 1$, since it implies that if the hamiltonian contribution $h$ does not depend explicitly on $k$, the hamiltonian will not be scale invariant by any EHM transformation in the $j^{th}$ dimension.

One can derive solutions of Eq. 20 by comparing terms power by power. For instance, the second-order terms in $h(w^2)$ on the LHS forces $h(w)$ to be a linear function of $w$ that is either symmetric or antisymmetric under $w \leftrightarrow w^{-1}$, i.e. a function of $w + w^{-1}$ or $w - w^{-1}$. Hence we find the two linearly independent solutions to Eq. 20 to be $h(z) = \frac{w + w^{-1}}{2} = \sin k$ and $h(z) = \frac{w - w^{-1}}{4} = \frac{1 - \cos k}{2}$. Both with the EHM rescaling $\lambda = \frac{1}{2}$. They are both gapless at $k = 0$, as they should be, and can be combined to form the massless Dirac Hamiltonian Eq. 12 in 1 + 1 dimensions:

\[
H_{\text{Dirac}}(k) = v_F [\sin k \sigma_1 + M(1 - \cos k) \sigma_2]
\]

(22)

where $\sigma_i$ are the Pauli matrices and $M$ controls the relative weightage of the two terms.

Note that the two terms $\sin k$ and $1 - \cos k$ do not have the same scaling dimension if one takes the continuum limit $\sin k \sim k$, $1 - \cos k \sim k^2/2$ in ordinary RG. This illustrates the distinction of real space EHM transformation from simple momentum rescaling, due to the nontrivial influence of lattice regularization that replaces functions in $k$-space with periodic trigonometrical functions.

### IV. ANALYTIC RESULTS FOR (1 + 1)-DIMENSIONAL BOUNDARY SYSTEMS

In Ref. 30, the behaviors of correlation functions and their associated bulk distances were studied numerically. In the following, we will obtain analytic results of the asymptotic behavior of bulk correlators for (1 + 1)-dim translationally-invariant boundary systems, which in turn determine the asymptotic large scale behavior of the
bulk geometry we define. We will compare them with the geodesic distances between analogous points in candidate classical geometries. The higher-dimensional extensions of these results will be discussed in the next section.

A. General setup

We shall consider four distinct physical scenarios, all at zero chemical potential, with the representation Hamiltonian for the first three cases taken to be the Dirac Hamiltonian given in Eq. 12. The results obtained should also be valid for more generic hamiltonians, since the qualitative bulk geometry properties remain robust as long as the long distance behavior of correlators remain the same. In approximately increasing levels of sophistication, the four scenarios are:

1. Critical boundary Dirac model at \( T = 0 \), corresponding to a bulk (Anti-de-Sitter) AdS geometry.

2. Massive boundary Dirac model at \( T = 0 \), corresponding to a “confined geometry” with an IR termination surface.

3. Critical boundary Dirac model at \( T \neq 0 \), corresponding to a bulk BTZ (Baados, Teitelboim, and Zanelli) black hole geometry.

4. Critical boundary model with nonlinear dispersion at \( T \neq 0 \), corresponding to a bulk Lifshitz black hole geometry.

The first two cases were already explored numerically in Ref. 30, with results in excellent agreement with our analytical results below.

As previously explained, the fundamental quantity to be calculated is the bulk correlator \( C(n_1, n_2, \Delta(2^n x), \tau) \) given in Eq. 18. In the thermodynamic limit \( L \rightarrow \infty \), all momentum sums can be replaced by integrals:

\[
C(n_1, n_2, \Delta(2^n x), \tau) = \sum_q W^*_n(q)W_n(q)e^{iq\Delta(2^n x)}G_q(\tau) = \oint_{|z|=1} \frac{dz}{z} W^*_n(z^{-1})W_n(z)z^{\Delta(2^n x)}G_z(\tau)
\]

where, as before, the conjugation symbol \(^*\) indicates that only the coefficients of the polynomial \( W(z) \) are complex conjugated. It is insightful to analytically continue the momentum \( q \) into the complex \( z = e^{i\theta} \) plane, where the decay properties of the correlators can be directly read from the properties of the complex poles and branch cuts.

For comparison with the geodesic distances, we shall specialize to 2-point correlators of the following three directions in the \((2+1)\)-dim bulk:

- Equal time, same layer “angular” correlator

\[
C_n(\Delta x) = C(n, n, \Delta x, 0) = \oint_{|z|=1} \frac{dz}{z} W^*_n(z^{-1})W_n(z)z^{2^n\Delta x}G_z(0)
\]

- Equal time, different layer “radial” correlator

\[
C(n_1, n_2) = C(n_1, n_2, 0, 0) = \oint_{|z|=1} \frac{dz}{z} W^*_n(z^{-1})W_n(z)G_z(0)
\]

- Same site imaginary-time correlator

\[
C_n(\tau) = C(n, n, 0, \tau) = \oint_{|z|=1} \frac{dz}{z} W^*_n(z^{-1})W_n(z)G_z(\tau)
\]

Here, we have assumed translational invariance in \( x \), which is necessary for defining the correlator in terms of a Fourier integral in the angular direction.

Next we specify the boundary Hamiltonian. We shall use the Dirac Hamiltonian

\[
H_{\text{Dirac}}(k) = v_F|\sin k\sigma_1 + M(m + 1 - \cos k)\sigma_2|
\]

from Eq. 12 for cases (1) to (3). For the sake of conciseness in the already sundry results, we shall henceforth set \( v_F \) and \( M \) to unity unless otherwise stated, and consider only cases at zero chemical potential \( \mu \). Indeed, \( v_F \), which couples to \( \tau \) under imaginary time evolution \( e^{-iH\tau} \) merely leads to a trivial rescaling \( \tau \rightarrow v_F\tau \) in the results. The value of \( M \) do not affect the leading asymptotic behavior of the correlators in general, and its study is relegated to Appendix E. For case (4), we shall simply base our calculations on the non-linear dispersion relation

\[
E_k = k^\gamma,
\]

since we will be primarily interested in the effect of setting \( \gamma \neq 1 \).

We next elaborate on the complex analytic structure of the Dirac Hamiltonian and correlator. The positions of the complex singularities play a crucial role in determining the asymptotic decay behavior of the correlators, typically with power-law decay when all singularities lie on the unit circle and exponential decay otherwise. The correlator in the spatial “angular” direction, in particular, is a Fourier transform for which there exists results that relate the decay of Fourier coefficients with the location of singularities. For a meromorphic function \( f(z) \), the Fourier coefficients \( f_l = \oint_{|z|=1} \frac{dz}{z} f(z)z^l \) decay like

\[
f_l \sim l^{-(1+B)|z_0|^l}
\]
for $|z_0| < 1$, $l \gg 1$, with $z_0$ the branch point of $f(z)$ closest to the unit circle and $B$ is its corresponding branching number:

$$f(z_0 + \Delta z) \sim f(z_0) + \left( \frac{\Delta z}{z_0} \right)^B$$

(28)

for $z$ near $z_0$. Note that $B$ cannot be a non-negative integer, since otherwise the Riemann surface will not be ramified at $z_0$. Proofs, together with other physical applications of this result, can be found in Refs. 44–46 and especially 47.

In our correlators of interest, $f(z)$ takes the explicit forms $h_z$ or $h_z / E_z$ defined below. $h_z$ is the Dirac Hamiltonian with $M = 1, v_F = 1$:

$$h_z = \begin{pmatrix} 0 & i(\frac{1}{z} - (1 + m)) \\ -i(z - (1 + m)) & 0 \end{pmatrix}$$

(29)

with eigenenergies

$$E_z = \sqrt{1 + (m + 1)^2 - (1 + m)} \left( z + \frac{1}{z} \right)$$

$$\longrightarrow_{m=0} -i(z^{\frac{1}{2}} - z^{-\frac{1}{2}})$$

(30)

Due to the square root, $z$ is a single valued function on a 2-sheeted Riemann surface with ramification points (branch points) at $z = \infty, m + 1, \frac{1}{m+1}$ and 0. When $m = 0$, the two points $z = (1 + m)^{±\frac{1}{2}}$ coincide and annihilate, leaving a single branch cut from 0 to $\infty$. These branch points also appear in the flattened hamiltonian $h_x / E_z$ that appears in the correlators Eqs. A6, A7 and A8:

$$\frac{h_x}{E_z} = \left( \begin{array}{cc} 0 & \sqrt{\frac{m+1}{z} \frac{1}{z-1}} \\ -\sqrt{\frac{m+1}{z}} & 0 \end{array} \right)_{m=0} = \left( \begin{array}{cc} 0 & \frac{1}{\sqrt{z}} \\ \sqrt{z} & 0 \end{array} \right)$$

(31)

When $m = 0$ at criticality, $\frac{h_x}{E_z}$ takes a particularly simple form that does not contain any nonzero pole in the unit circle. This still holds true for much more generic critical systems, being a necessary condition for power-law decay as required by Eq. 27. Note that all the nontrivial branch points in the integrand of the bulk correlator must come from $G(z)$, since the wavelet basis functions $W_n(z)$ or $W_n(z^{-1})$ are polynomials in $z$ or $\frac{1}{z}$.

Although we have only explicitly studied the complex topology of the Dirac model, the important point is that more generic models, i.e. multi-band models with arbitrary dispersion also have analogous topologies that lead to similar asymptotic correlator behavior. This will be further elaborated in the last part of Appendix E.

Table I contains a summary of the asymptotic behavior of the mutual information, correlators, Entanglement Entropy and bulk geometry parameters for the different boundary systems. More details about each case are discussed in the remainder of this section.

---

B. Critical boundary Dirac model vs. bulk AdS space

For a start, let us consider the massless $(1+1)$-dim massless Dirac model as the boundary theory. We show that the correlators in all the three directions (Eqs. 24 to 26) all suggest a bulk geometry of a $(2+1)$-dim Anti de-Sitter space (further detailed in Appendix I) given by the metric (Eq. I2):

$$\frac{1 + \rho^2 \tau^2}{1 + \frac{L^2}{4\pi^2} \tau^2} d\tau^2 + \frac{dr^2}{1 + \rho^2 \tau^2} + \rho^2 d\theta^2$$

(32)

where $L$ is the boundary system size and $\tau$ is scaled such that the metric is $O(2)$-invariant at the critical boundary where $\rho = \frac{L}{2\pi} \gg R$. In the following, we shall only consider asymptotically large angular and temporal intervals with $\Delta x, \tau \to \infty$, and/or not necessarily large radial intervals between layers 1 and $n$. Since we have already taken the thermodynamic limit $L \to \infty$, $\Delta x < L$ can still be satisfied for arbitrarily large $\Delta x$.

---

1. Spatial directions

As is detailed in Appendix A, the spatial decay of the Mutual Information is given by (see Eq. (A4)):

$$I_{xy} = \frac{4(|u|^2 + |v|^2)}{1 - 4A^2}$$

(33)

where $|u|, |v|$ are the off-diagonal (unlike spin) part of the propagator $C_{x-y}$, and $A$ is the off-diagonal part of the onsite propagator. From Eq. 29, they are explicitly:

$$A = -i C_n(\Delta x = 0) = i \int_{|z|=1} dz \frac{d}{dz} W_n^*(z^{-1}) W_n(z) \sqrt{z}$$

(34)

which, being onsite, does not depend on the displacement between $x$ and $y$. For the angular direction where $x, y$ are on the same layer,

$$u, v = -i C_n(\Delta x) = -i \int_{|z|=1} dw W_n^*(z^{-1}) W_n(z) z^{\frac{\Delta x}{2}} z^{2\Delta x}$$

(35)
while for the radial direction where \(n_1 \neq n_2\) but \(\Delta x = 0\),
\[
u v = -i C(n_1, n_2) = -i \int_{|z|=1} \frac{dz}{z} \left[ W_{n_1}^* (z^{-1}) W_{n_2} (z) \right]^{\mp}.
\]

In the above equations, the integrands do not contain poles. However, the integrals are nonzero due to the branch cut from \(z = 0\) to \(z = \infty\) from the square root factor. They can be evaluated by standard deformations of the contour, as demonstrated in detail in Appendix B.

After some computation, we obtain for the angular direction
\[
|u|, |v| \sim \frac{1}{16 \pi} \frac{1}{(\Delta x)^3}.
\]

As elaborated in Appendix B 1, such a power-law decay of the single-particle propagator is generally expected in the presence of a branch cut. Physically, it is a signature of criticality, with a power of 3 instead of 1 due to the additional ‘destructive interference’ from the antisymmetric combinations of adjacent sites in the Haar wavelet basis. There is a striking absence of the layer index \(n\) in Eq. 37, which reflects the scale-invariance of the boundary theory. Eq. 37 also holds for general values of \(M\) in the Dirac Model Eq. 12, where \(M\) controls the ratio between the quadratically dispersive \(1 - \cos k\) and linearly dispersive \(\sin k\) terms near the IR point. While \(M\) can affect the details of the branch cut, it cannot change the decay exponent, as shown in Appendix E.

For the radial direction with \(n_1 = 1\) and \(n_2 = n\), Appendix B 2 also tells us that
\[
|u|, |v| \sim \left( \frac{1}{\sqrt{2}} \right)^{n-1}.
\]

Hence we have exponential decay of the single-particle propagator in the radial direction, which is consistent with scale invariance.

Strictly speaking, the mutual information across the radial direction involves both \(A_1\) and \(A_n\), the unlike spins onsite propagators \(A\) at layers 1 and \(n\), and a more general (and complicated) version of Eq. (A4) should be used. However, \(A_n \to 0\) rapidly as \(n\) increases, effectively leading to no asymptotic correction. Mathemati-
cally, this is because as \( n \) increases, the peaks of \( W_n(e^{iq}) \) approaches a delta function at \( q_0 = \frac{2\pi}{\pi} \rightarrow 0 \) which gets exponentially closer to the IR point, where contribution are penalized by the momentum correlator \( \frac{h_n}{\xi_n} \). Explicitly,

\[
|A_n| = -\frac{i}{2} \int_{-\pi}^{\pi} |W_n(e^{iq})|^2 \text{sgn}(q)e^{in/2}dq \\
\rightarrow \frac{1}{2} \int_{-\pi}^{\pi} |W_n(e^{iq})|^2 |q| \frac{1}{2} dq \\
\sim \frac{1}{4} |W_n(e^{iq})|^2 \int_{-\pi}^{\pi} |q| dq \\
= \frac{2^{n-1}}{\pi} q_0^2 \\
= \frac{2}{\pi} 2^n \rightarrow 0
\]

in the large \( n \) limit. Physically, this means that unlike spins become totally decoupled in the IR regime. According to Eq. A5, the sites in the IR layers are hence maximally entangled with the rest of the bulk:

\[
S_x \rightarrow -\frac{1}{2} \log \frac{1}{2} = \log 4
\]

This maximal entanglement in the IR also exists in generic critical systems, since the IR DOFs become harder and harder to isolate unless an energy scale (i.e. mass) exists.

Putting it all together, the mutual information behaves like

\[
-\log I_n(\Delta x) \sim 6 \log \Delta x + \log(32\pi^2)
\]

for angular intervals and

\[
-\log I(1, n) \sim (n - 1) \log 2 + \text{small const.} \sim \Delta n \log 2
\]

for radial intervals. These asymptotic behaviors are in excellent agreement with those of the geodesic distances on AdS space, if one uses the proposed correspondence given by \( \frac{\Delta x}{\xi} = -\log \frac{1}{\xi} \) in Eq. 6. The parameters \( \xi \) and \( I_0 \) respectively set the scales of bulk distance and mutual information, and are related in a precise way discussed later. In principle, \( \xi \) can be different in different independent directions.

We first study the correspondence in the angular direction. The geodesic distance between two equal-time points \((\rho_1, \theta_1)\) and \((\rho_2, \theta_2)\) with angular interval \( \Delta \theta = |\theta_2 - \theta_1| = \frac{\Delta \theta}{\pi} \) is given by Eq. 14:

\[
d_{\Delta \rho}^{\text{min}} = R \cosh^{-1} \left( 1 + \frac{2\rho^2}{R^2} \sin^2 \frac{\Delta \theta}{2} \right) \sim 2R \log \frac{\Delta \rho}{\xi} \quad (43)
\]

where \( R \) is the AdS radius that determines the length scale below which we expect significant deviations from logarithmic behavior. Comparing Eqs. 41 and 43, we see that

\[
\frac{R}{\xi} = 3 \quad (44)
\]

and

\[
R = \frac{1}{2} \left( \frac{1}{\pi} \sqrt{\frac{2}{I_0}} \right) \tau
\]

We see that \( R \) decreases weakly with increasing \( I_0 \). For the Dirac model we take \( I_0 = 2 \log 4 \), the theoretical maximal mutual information mentioned below Eq. 6. With it, we obtain \( R = 0.3233 \) and \( \xi_\rho = 0.1078 \), which is in excellent agreement with the numerical values obtained in Ref. 30.

For the radial direction, we compare Eq. 42 with the AdS geodesic distance (Eq. 15):

\[
d_{\Delta \rho}^{\text{min}} = R |\Delta (\log \rho)| \\
= R |\log(2)| |\Delta n| \quad (46)
\]

Here we have taken \( \rho = \rho_n = \frac{L}{2\pi v_F}, \) as required by the scale-invariance of radius \( \rho \) and the circumference \( \frac{L}{2\pi} \) at any layer \( n \). We easily obtain

\[
\xi_\rho = R \quad (47)
\]

which means that the AdS radius is nothing but the radial length scale \( \xi_\rho \) of radial geodesics. This is also in agreement with the numerical results in Ref. 30.

It should be noted that the ratio \( R/\xi \) is different for the angular and radial directions, which is a manifestation of the fact that the mapping does not preserve the entire conformal symmetry of AdS space (since conformal symmetry is only emergent in long wavelength limit and does not exist rigorously in a lattice model). The bulk theory has scale invariance and a reduced translation symmetry with unit cell size varying with the layer index \( n \), but the correlations are anisotropic between radial and angle directions.

2. Imaginary time direction

As previously postulated by Eq. 7, we can deduce a classical bulk geometry from the decay properties of the imaginary time correlator \( C_n(\tau) \) given by

\[
C_n(\tau) = \frac{1}{2} \int_{-\pi}^{\pi} dq |W_n(e^{iq})|^2 e^{-\tau E_q} \left( 1 - \frac{h_q}{E_q} \right)
\]

When \( \tau \) is large, the value of \( C_n(\tau) \) arises from competing contributions from the IR regime and the momentum scale set by the layer index \( n \). While most of the spectral weight of \( W_n(e^{iq}) \) is concentrated around the momentum \( q_0 = \frac{2\pi}{\pi}, \) the exponential factor exponentially suppresses contributions above the IR regime set by \( E_q = v_F \tau \sim \tau^{-1}. \) Hence we expect \( C_n(\tau) \) to increase as \( n \) goes deeper into the IR. Indeed, this is exactly contained in the analytical result Eq. D6 derived in Appendix D:

\[
TrC_n(\tau) \sim \frac{1}{8\pi} \left( \frac{2^n}{v_F \tau} \right)^3 = \frac{1}{(8\pi^2)^2} \left( \frac{L}{v_F \tau} \right)^3
\]
where $\rho = \frac{L}{2\pi R}$ is the bulk radial AdS coordinate of layer $n$. Eq. 49 also holds for generic $M$ in the Dirac model (Eq. 12), except for the degenerate case where $M = \infty$ and there is no linearly dispersive term $\sin k\sigma_3$. Comparing the logarithm of Eq. 49 with the AdS time-like geodesic $d\tau \sim 2R \log \frac{2\pi \rho}{\tau R}$ from Eq. 16, we obtain
\[
R = \frac{3}{2} \xi_\tau \quad (50)
\]
and
\[
R_\tau = \frac{1}{2v_F \pi^{1/3}} \approx \frac{0.3414}{v_F} \quad (51)
\]
These results are valid in the regime where $\rho \gg R_\tau$ and $R_\tau \ll \tau \ll L$, i.e. when the geodesics do not come close to circumnavigating the AdS space. The AdS radius $R_\tau$ obtained here is slightly different from $R$ obtained through spatial geodesics in Eq. 45, with the latter containing a weak dependence on the reference mutual information $I_0^{-1/6}$.

\[
\frac{R_\tau}{\xi_\tau} = \frac{3}{2} \quad (52)
\]

This is our first and simplest example of a non-critical model (Eq. 12), except for the degenerate case where $M = \infty$. Comparing the logarithm of Eq. 49 with the AdS time-like geodesic $d\tau \sim 2R \log \frac{2\pi \rho}{\tau R}$ from Eq. 16, we obtain $R_\tau = \frac{1}{2v_F \pi^{1/3}} \approx \frac{0.3414}{v_F}$. For a Dirac model with a generic value of $M$ in Eq. 12, $z_0 = \frac{1}{1 + m}$ should be replaced by the pole

\[
z_0 = \frac{M(1 + m) - \sqrt{1 + 2mM^2 + m^2M^2}}{M + 1}, \quad (54)
\]

where $\frac{h_{\text{off diag}}}{E_q}$ is the $2 \times 2$ matrix given by Eq. 29. For the Dirac model with $m \neq 0$, $\frac{h_{\text{off diag}}}{E_q}$ and hence the integrand of Eq. 52 now has square root branch points away from the origin, namely at $z_0 = 1 + m$ and $z_0 = \frac{1}{1 + m}$. Unlike in the critical case, the singularity $z_0 = 1 + m$ now satisfies $|z_0| < 1$ and by Eq. 27 determines the asymptotic exponential correlator decay with $f(z) = W_n^*(z^{-1})W_n(z)\frac{1}{2\pi R} z^{2n}\Delta x$. The branching numbers $B$ (Eq. 28) at $z_0$ are given by $B = \pm \frac{i}{\sqrt{2}}$ for $u$ and $v$, which shall thus decay (for $2^n\Delta x \gg 1$) like

\[
u, v \sim \frac{(2^n\Delta x)^{-1+1/2}}{z_0}\approx \frac{e^{-m2^{-n}\Delta x}}{(2^n\Delta x)^{1+1/2}} \quad (53)
\]

We see that $v$ dominates with a factor of $2^n\Delta x$, and is itself an exponential decay with a subleading power-law decay. Hence $-\log I_{xy}$ will define a rescaled Euclidean distance with length scale given by $\frac{1}{m}$. For a Dirac model with a generic value of $M$ in Eq. 12, $z_0 = \frac{1}{1 + m}$ should be replaced by the pole

\[
z_0 = \frac{M(1 + m) - \sqrt{1 + 2mM^2 + m^2M^2}}{M + 1}, \quad (54)
\]

whose corresponding effective mass is given by $|z_0|^{-1} - 1$.

As contrasted with the critical case, the mutual information in the massive case also depends nontrivially on $A$, the unlike-spin onsite propagator, as we go deep into the IR regime below the energy scale of layer $n$. Recall that at layer $n$, $A$ is given by

\[
A_n = -\frac{i}{2} \int_{-\pi}^{\pi} |W_n(e^{i\eta})|^2 \frac{h_{\text{off diag}}}{E_q} dq \quad (55)
\]

For large $n$, the spectral weight is mainly concentrated around $q_0 = \frac{2\pi}{L}$, where

\[
\frac{h_{\text{off diag}}}{E_q} = \sin q \pm i(m + 1 - \cos q) \frac{E_q}{\sqrt{m^2 + q^2}} \approx i \left(1 + \frac{m - 1}{2m^2} q^2\right) \quad (56)
\]

where the $\sin k$ term had been dropped because it is odd. Hence Eq. 55 can be rewritten as

\[
|A_n| = \frac{1}{2} \int_{-\pi}^{\pi} |W_n(e^{i\eta})|^2 \left(1 + \frac{m - 1}{2m^2} q^2\right) dq \approx \frac{1}{2} + \frac{m - 1}{4m^2} \int_{q_0}^{\infty} |W_n(e^{i\eta})|^2 dq \approx \frac{1}{2} - \frac{1}{4m^2} \int_{-q_0}^{q_0} |W_n(e^{i\eta})|^2 dq \approx \frac{1}{2} - \frac{2^n q_0^3}{8m^2\pi^2} \frac{1}{3} \quad (57)
\]

1. Angular direction

As previously discussed, the geodesics in the spatial angular direction depend on the mutual information $I_{xy} = \frac{|u|^2 + |v|^2}{2\pi \xi_\tau}$ where $u$ and $v$ are the unequal-spin propagators between sites separated by an angular distance of $\Delta \varphi$ within layer $n$, and is the $A$ is the unlike-spin onsite propagator.

We first look at how $u$ and $v$ differ from those of the critical case. They are given by the off-diagonal components of

\[
-i \oint_{|z| = 1} \frac{dz}{z} W_n^*(z^{-1})W_n(z) z^{2n}\Delta x \frac{h_z}{E_z} \quad (52)
\]
This leads to an overall enhancement of $\frac{1}{\log 16} \sim 4^n$ in the mutual information, which thus behaves like

$$-\log I_n(\Delta x) \sim 2^{n+1} m \Delta x + \log \Delta x - n \log 2$$

(58)

Its leading contribution is proportional to $2^n \Delta x$, which leads to a key difference of its dual geometry from that of the critical fermion. Since the corresponding geodesic distance $d_{\Delta x} = \xi_{\Delta x} I_n(\Delta x)$ is linear in $\Delta x$, i.e. like an Euclidean distance, we can obtain the circumference $\alpha_n$ of layer $n$ simply by taking $\Delta x = 2^{N-n}$, the number of sites in the whole layer. More rigorously, the circumference $\alpha_n$ should be measured by first taking equally spaced points with $2^{N'}$ sites between them, and then taking the $N' \to \infty$ limit before taking the $N \to \infty$ limit. The circumference will be given by the product of the geodesic distance between neighboring points $2m\xi_{\Delta x} - 2^{n+N'}$ and the number of points $2^{N-n-N'}$, i.e. $\alpha_n = 2m\xi_{\Delta x} - 2^{N}$ which is a finite portion of the boundary circumference $2^{N}$.

The fact that $\alpha_n$ is finite in the large $n$ (infrared or IR) limit tells us that when $n \to \infty$, we are not approaching the center of a hyperbolic disk, but rather approaching a surface with finite area which acts as a “termination surface” of the space. This is illustrated in Fig. 3. The IR surface shrinks with decreasing mass $m$. By comparison, in the dual geometry corresponding to the critical fermion, the distance between points $\Delta x$ sites apart does not depend on the layer index, so that the circumference $\alpha_n \propto 2^{-n}$ decays exponentially in the IR limit.

It is important to note that this surface is not a black hole horizon, which distinguishes it from the case of nonzero temperature state we will discuss in subsequent sections. One evidence for this conclusion is that each site carries a vanishing entanglement entropy $S_x$ in the IR limit $n \to \infty$, since

$$S_x \approx \frac{2}{3m^2} \frac{1}{4^n} \left( \frac{1}{3m^2} \frac{1}{4^n} + \log \left( \frac{1}{3m^2} \frac{1}{4^n} \right) - 1 \right)$$

$$\sim \frac{\log 16}{3m^2} \frac{n}{4^n}$$

(59)

which is obtained by substituting Eq. 57 into Eq. A5. Since the entropy decays exponentially at large $n$, the IR sites actually for direct product states unentangled with one another. This is consistent with the physical picture that mass is renormalized to exponentially larger values in the IR limit (with respect to the kinetic energy scale), which forces the IR ground state to be simply a direct product of the single-site ground states of the a large mass term.

2. Imaginary time direction

The correlator in the imaginary time direction can be obtained pretty straightforwardly. Substituting the expression for the energy dispersion $E_q = \sqrt{\sin^2 q + (1 + m - \cos q)^2} \approx m + \left( \frac{1+m}{2m^2} \right) q^2$ into Eq. 48, we obtain

$$TrC_n(\tau) = e^{-m\tau} \int_{-\pi}^{\pi} dq W_n(e^{iq})^2 e^{-\frac{1+n}{2m^2} q^2}$$

(60)

which is an exponentially decaying term multiplied by a nonuniversal Gaussian Integral. Hence $-\log TrC_n(\tau) \sim m\tau$ defines an Euclidean bulk geodesic in the imaginary time direction. Together with the previous results on spatial geometry, we see that although there is a spatial termination surface in the IR limit, the temporal direction still extends as usual. This is consistent with our earlier statement that the IR termination surface is not a black hole horizon, since the time direction is not infinitely redshifted. Topologically, the spacetime we obtain for the massive Dirac model is $\mathcal{R} \times \mathcal{M}$, where $\mathcal{R}$ is the line in time direction, and $\mathcal{M}$ is a spatial annulus.

D. Critical linear boundary Dirac model at nonzero $T$ vs. bulk BTZ black hole

Now we study the effect of nonzero temperature in the massless Dirac model, the bulk geometry dual to which will be interpreted as a BTZ (Banados, Teitelboim and Zanelli) black hole. The BTZ black hole is a black hole solution for $(2+1)$-dimensional gravity with a negative cosmological constant.
logical constant, whose metric is

$$ds^2 = \frac{V(\rho)}{V(L/(2\pi))} dr^2 + \frac{d\rho^2}{V(\rho)} + \rho^2 d\theta^2$$

(61)

where \( V(\rho) = \frac{2\beta - \beta^2}{R^2} \) is the Laplace function, \( b \) is the horizon radius and \( R \) is an overall length scale. We have rescaled \( \tau \) by a factor of \( \left[V\left(\frac{L}{2\pi}\right)\right]^{-1/2} \) so that \( ds^2 \to dr^2 + \rho^2 d\theta^2 \) possesses \( O(2) \) symmetry at the boundary where \( 2\pi \rho = L \). The rescaling makes \( \tau \) the same imaginary time variable as that in the boundary Hamiltonian.

Most notably, we shall find that the layers deep in the IR accumulate at the bulk horizon radius \( \rho \to b \) from above, where \( b \) is proportional to the temperature \( T = \beta^{-1} \). This result is rigorously accurate in the \( m \sim O(1) \) range of the Dirac model given by Eq. 12, where the critical dispersion is essentially linear.

1. Angular direction

Like a nonzero mass, a nonzero temperature also introduces an energy scale into the system. This energy scale is manifested as an imaginary gap \(-\log|z_0| > 0 \) where \( z_0 \) is the singularity of the momentum-space correlator \( z_0 \) closest to the unit circle. In this case, the singularities originate from the \( \frac{\beta E_n}{2} \) term given in Eq. A8.

Above the energy scale of \( T \), all correlators and hence the mutual information do not feel the effect of thermal excitations, and define an approximate AdS geometry just as in the \( T = 0 \) critical case.

As one goes below the energy scale of \( T \), Eq. 27 states that the unlike-spin propagators \( u, v \) decay exponentially as \( |z_0|^{2n\Delta x} \), with a subleading power-law term \((2^n\Delta x)^{-(1+\beta)} \). \( B \) and \( |z_0| \) can be found as follows.

Expanding \( \cosh \frac{\beta E_z}{2} \), the denominator of the singular term, about \( z_0 \), we find that

$$\cosh \frac{\beta E_z}{2} \to 0 + \frac{\beta(z - z_0)}{2} \sinh \frac{\beta E_z}{2} \frac{dz}{dz} \propto z - z_0$$

(62)

so the branching number \( B = -1 \). This value of branching number holds universally for generic systems at nonzero temperature\(^{51}\), since Eq. 62 does not depend on the form of \( E_z \). Therefore, there is rigorously no subleading power-law term in the decay of correlators in the nonzero temperature case.

We now proceed to find \( |z_0| \), \( \tanh \frac{\beta E_z}{2} \) is singular when \( \cosh \frac{\beta E_z}{2} = 0 \), i.e.

$$\cosh \frac{\beta E_q}{2} = \beta E_q = -i\beta(z^{1/2} - z^{-1/2})$$

(see Eq. 30).

This satisfied by \( z + \frac{1}{z} = \left(\frac{2\pi(2l+1)}{\beta}\right)^2 \), where \( l \in \mathbb{Z} \). Hence the poles occur at

$$z^\pm_0 = 1 \pm \frac{\pi^2(2l+1)^2}{2\beta^2} \pm \frac{\pi(1+2l)\sqrt{4\beta^2 + (2l+1)^2\pi^2}}{2\beta^2}$$

$$\to 1 \pm \frac{2l+1}{\beta} \quad (63)$$

in the limit of small \( T = \frac{1}{\beta} \). The pole with \( l = 0 \) is closest to the unit circle, and we thus have the asymptotic decay

$$u \sim v \sim |z_0^-(l = 0)|^{2n\Delta x} \to (1 - \pi T)^{2n\Delta x} \approx e^{-\pi T 2^n \Delta x}$$

(64)

so that

$$I_n(\Delta x) \sim \frac{8e^{-\pi T 2^n \Delta x}}{1 - 4A_n^2}$$

(65)

Since \( A_n \to \frac{1}{2} \) after the first few \( n \), as explained in the subsection on the zero temperature critical case (1), the mutual information behaves like (recalling that \( 2^n \Delta x = \frac{L\Delta \theta}{2\pi} \))

$$-\log I_n(\Delta x) \sim 2\pi T 2^n \Delta x = LT \Delta \theta$$

(66)

with no logarithmic subleading term. This asymptotic form for \( I_n(\Delta x) \) is, to leading order, the same as that of Eq. (58) for the massive zero temperature case, if we replace \( 2m \) by \( 2\pi T \). Following along the same lines as the previous section, we conclude that the circumference of each circle at layer \( n \) is asymptotically \( \alpha_n \approx 2\pi T \cdot 2^n \).

Thus there is a termination surface with this circumference (1-dim area) in the IR (low energy) limit. However, as we will verify by the single-site entropy and imaginary time direction distance later in this section, this surface is not just a termination surface of space, but a black hole horizon. Before discussing that, we shall first make a detailed comparison of the angular direction distance defined by Eq. 66 with the angular geodesic distance given by a BTZ black hole metric.

We can obtain a precise relationship between the temperature \( T \) and the black hole radius \( b \). Since Eq. 66 holds in the IR regime, we compare it with the BTZ geodesic distance\(^{52}\)

$$d_{\Delta x}^{\text{min}} = 2R \sinh^{-1}\left(\frac{\xi \sin h b \Delta \theta}{2R}\right)$$

from Eq. 23 of Ref. 30 in the near horizon limit \( 0 < \rho - b \ll b \).

$$-\log I_n(\Delta x) = \frac{d}{\xi_\theta} = \frac{2R}{\xi_\theta} \sinh^{-1}\left(\frac{\rho \sin h b \Delta \theta}{2R}\right)$$

$$\approx \frac{2R}{\xi_\theta} \log \left(\frac{\rho}{b} e^{b \Delta \theta/2R}\right)$$

$$= \frac{2R}{\xi_\theta} \log \frac{\rho}{b} + 2\pi b \log \frac{\Delta x}{\xi L}$$

(67)

which implies that

$$b = L\xi_\theta T$$

(68)

Here \( \xi_\theta \) is a yet-underdetermined length scale. Our bulk geometry has agreed remarkably well with that of an actual BTZ black hole, with the LHS and RHS of Eq. 67 agreeing on not just the leading term linear in \( \Delta x \), but also the vanishing logarithmic subleading term. Further
discussions of the near-horizon geometry can be found in Appendix I 2.

ξb can be determined by comparing Eq. (68) with the relation between \( T \) and \( b \) in classical gravity. The requirement that the geometry is smooth in imaginary time at \( \rho = b \), i.e. without a conical singularity, requires\(^{53,54}\)

\[
T = \left( \frac{2\pi R^2}{b} - \frac{L}{2\pi R} \right)^{-1} = \frac{b}{RL} \tag{69}
\]

More details about this formula are given in Appendix I 2. Comparing Eqs. (68) and (69) we obtain

\[
R = \xi_b
\tag{70}
\]

so that \( \xi_b \) and \( R \) are actually one and the same length scale parameter.

2. Imaginary time direction

The nonzero temperature features prominently in the imaginary time correlator because a finite \( \beta \) corresponds to a finite periodicity in imaginary time. We shall show that the correlator \( TrC_n(\tau) \) defines a bulk geometry that is qualitatively similar to that of BTZ black hole, and deduce the effective radius \( \rho = \rho_n \) of layer \( n \) by looking at the maximal value of \(-\log TrC_n(\tau)\) achieved at half-period \( \tau = \frac{\beta}{2} \).

The quantity to be computed is

\[
TrC_n(\tau) = \frac{1}{2} \int_{-\pi}^\pi dq |W_n(e^{iq})|^2 TrG_q(\tau)
\tag{71}
\]

where, from Eq. 17,

\[
TrG_q(\tau) = \sum_{\lambda_q} \frac{e^{\lambda_q \tau}}{1 + e^{\beta\lambda_q}} = \frac{1}{2} \sum_{\lambda_q} \frac{e^{\frac{\beta q}{2}}}{1 + \cosh \frac{\beta \lambda_q}{2}} = \frac{\cosh \eta E_q}{\cosh \frac{\beta E_q}{2}} \tag{72}
\]

where \( \eta = \tau - \frac{\beta}{2} \) and \( \lambda_q \) denotes an eigenenergy of the system. The intermediate steps of Eq. 72 are valid for any number of bands, but we have specialized to \( \lambda_q = \pm E_q \) for the particle-hole symmetric 2-band case at the last step. \( TrG_q(\tau) \) is manifestly even in \( \eta \), which guarantees that \( TrG_q(0) = TrG_q(\beta) \). It can also be obtained from Eq. A6 through direct simplification.

Due to the presence of the energy scale set by \( T \), there are two distinct regimes. In the (high energy) UV limit \( \lambda_n \ll 2\pi R \) the kinetic energy dominates the temperature, and we have \( \cosh \eta E_q \approx \cosh \frac{\beta E_q}{2} \approx e^{-\tau E_q} + e^{(\tau-\beta)E_q} \), yielding the nice relation

\[
TrC_n(\tau) \approx TrC_n(\tau)|_{\tau = 0} + TrC_n(\beta - \tau)|_{\tau = 0}. \tag{73}
\]

This equation tells us that the nonzero temperature correlator above the energy scale of \( T \) is just the superposition of two copies of the zero temperature correlator reflected about \( \tau = \frac{\beta}{2} \). This is consistent with how correlation functions in BTZ geometry are obtained by a periodic quotient of those in AdS space\(^{55} \). Eq. 73 is completely general, since we haven’t used any particular form for the Hamiltonian.

Inserting the result of \( TrC_n(\tau)|_{\tau = 0} \) from Eq. 49, we find that

\[
-\log TrC_n(\tau) = -\log (\tau^{-3} + (\beta - \tau)^{-3}) - 3(n - 1) \log 2 + \log(\pi) \tag{74}
\]

As suggested in Fig. 4, the first term gives a qualitatively similar curve as the geodesic distance outside a BTZ black hole where \( \rho \gg b \):

\[
d_\tau = R \cosh^{-1} \left[ \frac{2\rho^2}{b^2} \sin^2 \frac{\pi \tau}{\beta} \right] \tag{75}
\]

which is derived in the Appendix of Ref.\(^{30} \).

FIG. 4. \(-\log trC_n(\tau)\) according to Eq. 74. Plotted are the \( n = 1, 2 \) curves for \( T = 0.005 \), which corresponds to an energy scale of \( n \approx 10 \).

We can find the length scales \( R \) and \( \xi_\tau \) by comparing the maximal value of \(-\log TrC_n(\tau)\) with \( \frac{d_\tau}{\xi_\tau}, \tau = \frac{\beta}{2} \). We have

\[
\frac{d_\beta/2}{\xi_\tau} = \frac{R}{\xi_\tau} \cosh^{-1} \left[ \frac{2\rho^2}{b^2} \right] \approx \frac{2R}{\xi_\tau} \log \frac{2\rho}{b} = \frac{2\rho}{\xi_\tau} \log \frac{2\rho}{bL} \approx \frac{2R}{\xi_\tau} \log \left( \frac{\beta}{L\pi^2/2} \right) \tag{76}
\]

where we have used \( \rho = \rho_n \approx \frac{L}{2\pi^2} \) in the approximate AdS geometry far from the horizon. Comparing this with \(-\log TrC_n(\beta/2) = 3 \log \frac{\beta}{\pi^2} + \log \frac{\pi}{2} \), we obtain

\[
\frac{R}{\xi_\tau} = \frac{3}{2} \tag{77}
\]
which is exactly the same as in the $T = 0$ case. This must be true because the bulk geometry is still asymptotically AdS above the energy of $T$. However, the value of $R$ is somewhat different due to the different functional forms of Eqs. 74 and 75, and takes the value

$$R = \frac{3}{\sqrt{2\pi^4}} \approx 0.274$$  \hspace{1cm} (78)$$

In the IR limit below the energy scale of $T$, i.e. $2^n > 2\pi\beta$, Eqs. 73 and hence 74 no longer hold because we must use the small $\beta E_q$ approximation in the denominator of $TrG_q(\tau) = \frac{\cosh \pi E_q}{\cosh \frac{\pi \tau}{2}}$. At $\tau = \frac{\beta}{2}$ or $\eta = 0$, we have, to 2nd order in $\beta E_q \ll 1$,

$$TrG_q(\tau = \beta/2) \approx \sum_{\lambda_q} 1 - \frac{\beta^2 \lambda^4_q}{8} \approx 1 - \frac{\beta^2}{8} q^2$$  \hspace{1cm} (79)$$

Hence,

$$-\log TrC(\beta/2) = -\log Tr \int dqG_q(\beta/2)|W_n(e^{iq})|^2$$

$$= -\log \left( \int dq|W_n(e^{iq})|^2 - \frac{\beta^2}{8} \int dq dq|W_n(e^{iq})|^2 \right)$$

$$\approx -\log \left( 1 - \frac{\beta^2}{8} \rho_0^2 |W_0(e^{i\rho_0})|^2 \right)$$

$$\approx \frac{\beta^2}{2^n \pi}$$  \hspace{1cm} (80)$$

where we have used the fact that $W_n(e^{iq})$ is sharply peaked at $q_0 = \frac{2\pi}{\beta}$ with magnitude $\sqrt{\frac{2\pi}{\beta}}$. Comparing Eq. 80 to the BTZ geodesic distance in Eq. 75:

$$-\log TrC(\beta/2) \sim 2R_\tau \cosh^{-1} \frac{\rho}{b} \approx \frac{3}{2} \sqrt{2 \left( \frac{\rho}{b} - 1 \right)}$$  \hspace{1cm} (81)$$

we arrive at

$$\rho_n \propto b \left( 1 + \frac{2}{9\pi^2} \frac{\beta^4}{2^{2n}} \right)$$  \hspace{1cm} (82)$$

Indeed, $\rho \to b$ exponentially from above. This justifies the previous assumption that $\frac{\rho}{b} - 1 \ll 1$ which is, among other implications, consistent with the fact that non-negligible logarithmic subleading terms exist in Eq. 67. Physically, the agreement between the imaginary time distance of the bulk geometry and the BTZ black hole means that the rate of imaginary time correlator decay slows down exponentially as one goes deeper into the IR, which translates into the infinite redshift an outside observer sees for any physical process near the BTZ horizon.

### E. Critical boundary model with nonlinear dispersion vs. bulk Lipshitz black hole

As a sequel to the previous subsection, we now consider a nonzero temperature boundary system with nonlinear dispersion in the long wavelength limit. As we have seen in the previous subsection, the energy-momentum dispersion is sufficient for determining the decay properties of the correlators. Here we consider the simplest nonlinear critical dispersion

$$E_q \approx q^7, \text{ for } q \approx 0$$  \hspace{1cm} (83)$$

For higher $q$, $E_q$ should be regularized to a periodic function. However, the details of the regularization do not affect the critical behavior as we have seen time and again, and Eq. 83 is sufficient as it stands. In this sense, Eq. 83 subsumes the Dirac model (Eq. 12) with general $M$, which is merely an interpolation between a $\gamma = 1$ and a $\gamma = 2$ hamiltonian.

The asymptotic behavior of the mutual information depends solely on the position of the singularities of $G_q(\tau) \propto \frac{1}{\cosh \frac{\pi \tau}{2}}$. They occur when $\beta E_q = i(2l + 1)\pi$, $l \in \mathbb{Z}$, i.e. when

$$E^2_q = q^{2\gamma} = -\pi^2 T^2 (2l + 1)^2$$  \hspace{1cm} (84)$$

In terms of $x = e^{iq}$, they occur at $z_0 = e^{(i\pi T(2l+1)/\gamma)}$. Clearly, the $l = 0$ singularity has the largest magnitude within the unit circle, which is given by

$$|z_0| = e^{-(\pi T)/\gamma \sin \frac{\pi}{2\gamma}}$$  \hspace{1cm} (85)$$

From Eq. 27 and discussions surrounding Eqs. 65, we conclude that the mutual information between two points with angular separation of $\Delta x$ sites decay like

$$-\log I_n(\Delta x) \sim 2(\pi T)^{1/\gamma}(2^n \Delta x) \sin \frac{\pi}{2\gamma} = \frac{L \Delta \theta}{\pi} (\pi T)^{1/\gamma} \sin \frac{\pi}{2\gamma}$$  \hspace{1cm} (86)$$

Similar to case (3) with linear dispersion, the $\Delta \theta$ dependence in the mutual information suggests that the circumference approaches a finite value in the IR limit, so that there is an event horizon. However, the nonlinear dispersion leads to a different $T$ dependence. Since the bulk geodesic distance $\Delta = -\log I_n(\Delta x) \propto T^{1/\gamma} \Delta \theta$, the black hole radius is $b \propto T^{1/\gamma}$, different from the $b \propto T$ behavior of the BTZ black hole.

There are indeed black holes solutions to classical gravity with the property $b \propto T^{1/\gamma}$, if one considers spacetimes with anisotropic scale invariance, i.e. with metric

$$ds^2 = -\frac{r^{2\gamma}}{R^{2\gamma}}dt^2 + \frac{R^2}{r^{2\gamma}} dr^2 + \frac{r^2}{R^{2\gamma}} d\vec{x}^2$$  \hspace{1cm} (87)$$
invariant under the rescaling \((t, \vec{x}, r) \rightarrow (\lambda^\gamma t, \lambda \vec{x}, \lambda^{-1} r)\), with \(\gamma\) the dynamical critical exponent and \(R\) a length scale.

If we include quadratic curvature tensor terms like \(\Omega^2\), \(\Omega_{\alpha\beta} \Omega^\alpha \Omega^\beta\) or \(\Omega_{\alpha\beta\mu\nu} \Omega^{\alpha\beta} \Omega^{\mu\nu}\) to the gravitational action\(^{57,58}\), the resultant Einstein’s equations in the non Galilean-invariant spacetime will possess black hole solutions for certain ranges of parameters. Such solutions are known as Lifshitz Black Holes, which are well-studied\(^{57-60}\) and proposed as possible gravity duals to Lifshitz fixed points in condensed matter physics. The explicit solutions of these black holes are known for certain values of \(\gamma\), especially in the 2 + 1 dimensions relevant to our current context. For instance, the black hole metric for \(\gamma = 3\) and the gravitational action \(S = \frac{1}{2\pi\ell}\int d^3x \sqrt{-g} \left[ \Omega - 2\Gamma + 2R^2 \left( \Omega_{\alpha\beta} \Omega^{\alpha\beta} - \frac{2}{3} \Omega^2 \right) \right]\), where \(\Gamma\) is the cosmological constant, is given by\(^{57}\)

\[
ds^2 = -\frac{\rho^6}{R^6} \left( 1 - \frac{b}{\rho^2} \right) dt^2 + \frac{R^2 \rho^2}{\rho^2 - b^2} + r^2 d\theta^2 \quad (88)
\]

By examining the near-horizon geometry in Euclidean time, we explicitly find its Hawking temperature to be \(T = \frac{b^3}{2\pi R^2}\), which agree with the horizon area we obtained from a boundary theory with cubic dispersion.

The \(T \propto b^7\) dependence can also be expected from a simple counting argument. A system at a temperature \(T\) can be physically understood as one with states randomly distributed in a energy width of \(T\). This randomness is quantified by the entanglement entropy \(S\) of the system with the thermal bath, most of which is carried by the IR region of the system. In the bulk system obtained through the EHM, the IR states carry maximal entropy per each site, so that the thermal entropy is proportional to the number of sites in the “stretched horizon”, which is proportional to the horizon area \(a\). For a system with energy dispersion \(E \propto q^\gamma\), the momentum range that has energy below \(T\) is \(\Delta k \propto T^{1/\gamma}\), so that the entropy \(S \propto \Delta k \propto T^{1/\gamma}\). Consequently, \(b \propto T^{1/\gamma}\).

The imaginary time bulk correlator behaves in a similar way as that with linear dispersion (Case (3)). For the layers with energy scale above \(T\), we still have, of course,

\[
TrG_n(\tau) = Tr[C_n(\tau) + C_n(\beta - \tau)]_{T=0}
\]

which holds independently of the dispersion. In the IR limit with energy scale below \(T\), the minimal value for \(TrG_\alpha(\tau)\) at \(\tau = \frac{2}{\beta}\) still follows from Eq. 79 and 80, except that the energy eigenvalues are now \(\lambda = q^\gamma\). Hence we obtain a nontrivial (but still simple) nonlinear correction

\[
-\log TrC(\beta/2) \sim \frac{\beta^2}{2^{(2\gamma - 1)n\pi}} \quad (89)
\]

which is consistent with the metric in Eq. 88, which has the geodesic distance at \(\tau = \frac{2}{\beta}\) vanishing as a power of \(\rho^{-b}\). We still have \(\rho \rightarrow b\) exponentially as \(n\) increases, but at a different rate compared to the BTZ (Galilean-invariant) case.

V. GENERALIZATION OF EHM TO HIGHER DIMENSIONS

A. General setup

When we generalize the boundary system to \(D\) spatial dimensions, the bulk system will contain \(D + 1\) spatial dimensions, with a new emergent direction representing the energy scale. The boundary theory and bulk theory can be related by EHM in the same way as in the \(D = 1\) case. For example, with a boundary theory defined on the two-dimensional square lattice, a unitary mapping can be defined on four sites around a plaquette, which maps it to two sites representing the high energy and low energy degrees of freedom of the four sites. The mapping is illustrated in Fig. 5. If the Hilbert space dimension is \(\chi\) on each site, the output IR site should have dimension \(\chi\) while the UV site now has a higher dimension \(\chi^3\), corresponding to the UV, IR, IR, IR, UV and UV, UV, UV sectors of the 1-dim case. More generally in \(D\) dimensions with a square lattice, one can map the \(\chi^D\) sites in a cube to one IR site with Hilbert space dimension \(\chi\) and one UV site with dimension \(\chi^{D-1}\).

For free fermions systems, the mapping is equivalent to a wavelet transformation on the single-particle wavefunctions, just like in the case with 1 spatial dimension. The simplest higher-dimensional wavelet basis can be obtained via direct products of 1-dim wavelet bases. To define them, we first label the 1-dim wavelet functions as

\[
W_n^\nu(z) = \begin{cases} 
C(z^{2^{n-1}}) \Pi_{j=1}^{n-1} C(z^{2^{j-1}}), & \nu = 1 \\
D(z^{2^{n-1}}) \Pi_{j=1}^{n-1} C(z^{2^{j-1}}), & \nu = 2 
\end{cases} \quad (90)
\]

so that \(\nu = 1, 2\) corresponding to the IR and UV wavelets in layer \(n\), respectively. The \(D\)-dimensional wavelet functions can then be defined by

\[
W_n^{\nu_1 \nu_2 \cdots \nu_D}(z_1, ..., z_D) = \prod_{j=1}^{D} W_n^{\nu_j}(z_j) \quad (91)
\]

These \(2^D\) wavefunctions for \(\nu_j = 1, 2\) include one IR wavelet defined by \(\nu_j = 1\), \(\forall j\) and \(2^D - 1\) other wavelets that are regarded as UV degrees of freedom. The bulk correlators \(C_{\mu\nu}\) can be obtained from the boundary correlator \(G_q(\tau)\) via this basis transform:

\[
C_{\mu\nu}(n_1, n_2, \Delta(2^n x), \tau) = \sum_q W_{n_1}^{\mu}(q) W_{n_2}^{\nu}(q) e^{i q \Delta(2^n x)} G_q(\tau) \quad (92)
\]

where we have denote the \(2^D - 1\) dimensional label of UV states \(\nu_1 \nu_2 \cdots \nu_D\) (with at least one \(\nu_j = 2\)) by \(\mu\) or \(\nu\) for simplicity.
When there is 8 number of orbitals at each site, the correlation matrix is \((2^D - 1)8 \times (2^D - 1)8\). For analyzing the asymptotic bulk geometry, it suffices to consider only the slowest decaying elements of \(C^{ij}\), which is determined by the lowest power of \(q\) in \(W_n^\mu(n)\). Using the long wavelength asymptotic behavior \(C(e^{iq}) \approx \sqrt{2}\) and \(D(e^{iq}) \approx \frac{\sqrt{2}q}{\sqrt{2}}\), we see that among the \(2^D - 1\) UV wavelets \(W_n^{1,2,\ldots,2^D}(q)\), the ones that play a leading role in the long wavelength correlation functions are those with only one \(v_j = 2\) and all other \(v_k = 1\), \(k \neq j\). Therefore the asymptotic behavior of the bulk correlator is given by

\[
C^{ij}(n, n, \Delta X, \tau) \sim 2^{D(n-2)} \partial_{X_j} \partial_{X_k} \sum q e^{iq\Delta X} G_q(\tau)
\]

(93)

where \(X_j = 2^nx_j\), and \(j, k\) are the directions where a 1-dim UV wavelet function \(D\) is taken, i.e., \(v_j, v_k = 2\).

In the following, we shall examine the bulk geometries of various critical boundary systems at both zero and nonzero temperature, and highlight how they are different from those of (1 + 1)-dim boundary systems.

### B. Critical boundary model at zero \(T\)

Here, we shall examine in detail the decay properties of the bulk mutual information and bulk imaginary time correlator corresponding to a critical \((D+1)-d\) boundary system. We will find that they describe a bulk geometry of a higher-dimensional AdS space, in close analogy to the (1 + 1)-dim case described previously. Similar to one-dimensional case, we consider the Dirac model in \((D+1)\)-dimensions:

\[
H = \sum_k \sum_{i=1}^D \left[ \Gamma^i \sin k_i + \left( M + D - \sum_{i=1}^D \cos k_i \right) \Gamma^0 \right] c_k
\]

(94)

where \(\Gamma^0, \Gamma^i\) are Hermitian Dirac matrices satisfying \(\{\Gamma^\mu, \Gamma^\nu\} = \delta^{\mu\nu}\) for \(\mu, \nu = 0, 1, \ldots, D\). For \(M\) close to 0, the lowest energy excitations of this system are centered around \(k = 0\), where the EHM defined by wavelets in Eq. (90) and (91) correctly separates low energy and high energy degrees of freedom. In the following, we study the behaviors of the correlation function and dual geometry along different directions. For simplicity, we shall only explicitly study the \((2 + 1)\)-dim case.

#### Spatial (angular) directions.

We build on the results of the decay of unlike spin propagators \(u, v\) for \((1 + 1)\)-dim, with two obvious extensions mandated by Eq. 93. Firstly, we now need to perform a multi-dimensional sum over \(q\) and secondly, we need to decide which sequence of derivatives \(\partial_{X_i}\) produce the slowest decaying correlator.

We recall that in the absence of a EHM transform, the critical correlator behaves like the inverse first power of distance, i.e. \(\sim \frac{1}{\sqrt{x^2 + y^2}}\). Under the EHM transform, the correlators \(u\) or \(v\) decay faster due to derivatives introduced by UV projectors \(D(e^{iq})\). Their slowest-decaying elements involve \(D = 2\) derivatives of either \(\partial_X\) or \(\partial_Y\). Hence

\[
|u| \sim |v| \sim \frac{1}{(x^2 + y^2)^{3/2}}
\]

(95)
i.e.

\[
I_n(\Delta x) \sim 6 \log |\Delta x| + \text{const.}
\]

(96)

which is an almost trivial generalization of the result in (1+1)-dim (Eq. 41). The undetermined constant defines the AdS radius of the corresponding AdS geometry, and is a complicated function of the full correlator involving \(u \sim v\). Here, we have not been careful in keeping track the powers of \(2^n\); readers interested in doing so are invited to generalize the more rigorous derivation in Appendix B. The apparent isotropy of Eq. 96 may not be exact due to the numerous approximations made. However, any angular dependency should only manifest itself as a form factor in the correlators, with the leading log term in the mutual information remaining unaffected.

#### Imaginary time direction.

A critical \((D+1)\)-d boundary system also has power-law decaying imaginary time correlators, consistent with the interpretation of the bulk as a higher-dimensional AdS spacetime. Explicitly,

\[
Tr C_n(\tau) \sim \left( \frac{2^{n-1}}{v_F^D}\right)^{D+2}
\]

(97)

with dimension-dependent critical exponent of \(D + 2\). This is unlike that of the spatial correlators, which does not depend on \(D\). Interpreted as a bulk geodesic distance \(d_x\), we have

\[
\frac{d_x}{\xi_\tau} = -\log Tr C_n(\tau) = (D+2) [\log(v_F \tau) - n \log 2] + \text{const.}
\]

(98)
which is proportional to the dimensionality. Physically, we can understand the origin of the $D + 2$ exponent as follows. Each spatial direction provides an additional dimension for the decay, and contributes a power of $\frac{2^n}{v_{F,T}} \propto \frac{L}{v_{F,T}}$. There has to be at least one direction where only the UV half of the degrees of freedom are selected, since a separation of energy scales is necessary for the EHM network. This direction contributes an additional power of 2 due to the gradient-like property of the UV projector $D(z)$. The above statements are justified with more mathematical rigor in Appendix F 1, where the subleading powers in the decay are also explicitly evaluated.

C. Boundary model with generic dispersion at nonzero $T$

When an energy scale is introduced by the temperature $T$, the decay of correlators is dominated by the energy scale which is independent of the EHM basis. Hence we can calculate the bulk correlators in a way similar to that of the $(1 + 1)$-dim case, taking note only of the multidimensionality of $q$.

Instead of just analyzing the Dirac model, we make our discussion more general by allowing our energy dispersion to take the following generic asymptotic form:

$$E_q = \sqrt{\sum_{j} v_j^2 q_j^{2\gamma_j}}$$  \hspace{1cm} (99)

This form encompasses various physical scenarios, and reduces to the linear Dirac model in the simplest case of $\gamma_j = 1$. When $D = 1$ and $\gamma > 1$, Eq. 99 represents the nonlinear dispersions discussed previously. More interestingly, it can also describe semi-Dirac points characterized by anisotropic dispersions, i.e. with $D = 2$, $\gamma_1 = 1$ and $\gamma_2 = 2$. Such dispersions have been observed in realistic systems involving ultrathin (001) VO$_2$ layers embedded in TiO$_2$, which exhibit unusual electromagnetic properties.

According to Eq. 27 and subsection IV D, the correlators and hence mutual information decay exponentially according to the complex root of $\cosh \frac{\beta E_{\delta x}}{2} = 0$ closest to the real axis. The roots are given by the solutions of

$$E_q^2 = -\pi^2 T^2 (2l + 1)^2$$

with $l \in \mathbb{Z}$, with the temperature $T$ functioning as an imaginary part. To find the exponential decay rate in direction $j$, we have to find $|Im(q_j)|$, the imaginary part of the complex root $q = q_j$ of

$$v_j^2 q_j^{2\gamma_j} = -(m^2 + \pi^2 T^2 (2l + 1)^2)$$  \hspace{1cm} (100)

where $m^2 = \sum_{i \neq j} v_i^2 q_i^{2\gamma_i}$ denotes an effective mass from the momentum contributions from all the other directions. Since $T^2$ and $m^2$ are both positive, we clearly require $l = 0$ for $q_j$ to have the smallest imaginary part, i.e. slowest decay. While the decay rate also depends on $m$, the combination of momentum components giving $m = 0$ yields the slowest decay rate $|Im(q_j)|$. We can take $m = 0$ to be the dominant contribution to the overall decay rate $h_j$, and the $m > 0$ contributions as the subleading corrections. This will be discussed explicitly for the two cases below, with calculational details relegated to Appendix C 1.

1. Finite temperature Dirac fermions

We first discuss the massless Dirac case with

$$E_q = v |q| = v \sqrt{\sum_{j} q_j^2}$$  \hspace{1cm} (101)

i.e. with $v_j = v$ and $\gamma_j = 1$ for $j = 1, 2, \ldots, D$. Let $\Delta \delta x$ be the displacement between two distant points within the same layer in the bulk. The mutual information decays like $I_{xy} \sim 8|u|^2 \sim 8|v|^2$ where, as shown in Appendix C 1,

$$u \sim v \sim e^{2\alpha q \Delta \delta x} \tanh \frac{\beta E_{\delta x}}{2} \frac{d^D q}{2}$$

$$\sim e^{-\frac{2\pi T}{\beta} \Delta \delta x}$$  \hspace{1cm} (102)

Hence

$$-\log I_n(\Delta \delta x) \sim \frac{2n+1}{v \sqrt{u}} \frac{\Delta \delta x}{\beta} = \frac{LT}{v} \sqrt{\sum_{j} (\Delta \theta_j)^2}$$  \hspace{1cm} (103)

This is a direct generalization of Eq. 66 for the $(1+1)$-dim critical Dirac model at temperature $T$, whose bulk geometry corresponds to that of a BTZ black hole horizon in the IR limit. Here, we have exactly the same asymptotic behavior, with the horizon having the same topology as the boundary system. When the latter is defined on a D-dimensional lattice with periodic boundary condition along all directions, the horizon is a D-dimensional torus $T^D$.

2. $(2 + 1)$-dim anisotropic dispersion

We now consider a generic anisotropic dispersion in $D = 2$, and show that the event horizon can also become anisotropic. The dispersion is given by

$$E_q = \sqrt{v_1^2 q_1^{2\gamma_1} + v_2^2 q_2^{2\gamma_2}}$$  \hspace{1cm} (104)

with correlator decay rates

$$\left(\frac{\pi^2 T^2 + v_{j'}^2 q_j^{2\gamma_j}}{v_j^{2\gamma_j}}\right)^{\frac{1}{2\gamma_j}} \sin \frac{\pi}{2\gamma_j}$$

where $j' = 1, 2$ for $j = 2, 1$. It is mathematically tricky to
obtain the asymptotic behavior of $I_{xy}$ for arbitrary $\Delta \vec{x}$, where all components of $\vec{x}$ are not small. For our current purpose, it suffices to expand the asymptotic behavior about the limiting directions $\Delta \vec{x} = x \hat{e}_x$ and $y \hat{e}_y$. After a Gaussian integral computation detailed in Appendix C 1, the mutual information at $\Delta \vec{x} = |\Delta \vec{x}|(\cos \phi \hat{e}_x + \sin \phi \hat{e}_y)$ for $\phi$ near 0 is approximately given by

$$- \log I_{xy}(\Delta x)|_{\phi \approx 0} \sim 2^{n+1} \left( \sin \frac{\pi}{2\gamma_1} \frac{\pi T}{v_1} x^2 + \frac{\gamma_1 (\pi T)^{2-1/\gamma_1} v_1^{1/\gamma_1} y^2}{2 \sin \frac{\pi}{2\gamma_1} \frac{v_1}{v_2} x} \right)$$

$$= 2^{n+1} |\Delta \vec{x}| \sin \frac{\pi}{2\gamma_2} \frac{\pi T}{v_1} x^2 \left( 1 + \frac{(\alpha_j^2 - 1)}{2} \phi^2 + O(\phi^4) \right)$$

(105)

where $\alpha_j = \sqrt{\gamma_j (\pi T)^{1-1/\gamma_j} v_j^{1/\gamma_j}}$. An exactly analogous result holds near $\phi \approx \pi$, with $\gamma_1$, $\alpha_1$ and $v_1$ replaced by $\gamma_2$, $\alpha_2$ and $v_2$.

Notably, in the isotropic linear Dirac case where $\gamma_1 = 1$ and $v_1 = v_2$, $\alpha_j = 1$, the mutual information is manifestly asymptotically isotropic to third order by Eq. 105. This is despite the fact that the wavelet basis was constructed via tensor products of those of each direction and hence only possess four-fold rotation symmetry.

By contrast, when the dispersion acquires some nonlinearity, $\gamma_j > 1$ and $\alpha_j \neq 1$ for some $j$, and we expect the mutual information to be significantly anisotropic in a temperature dependent way. This is illustrated in Fig. 6, where the angular dependence of the mutual information is compared for $\alpha = 1$ and 2. In any case, the factor $2^{n+1} |\Delta \vec{x}|$ in Eq. (105) suggests that there is still a finite area (anisotropic) horizon in the IR limit, since the circumference of a closed circle around any periodic direction approaches a finite value while $n \to \infty$.

VI. CONCLUSION

In this work, we have analytically studied the emergent bulk geometries of several different boundary systems through the EHM approach. In general, critical boundary systems at zero temperature correspond to scale invariant bulk geometry. A spatial boundary appears at infrared region where a mass scale is introduced by nonzero mass. At finite temperature, a horizon appears in the infrared region, which is distinguished from the spatial boundary by the infinite red-shift that can be observed in the behavior of correlation functions along the imaginary time direction. For critical boundary theories with different dynamical exponents, the spatial geometry is similar but the space-time geometry depends on the dynamical exponent, at both zero temperature and finite temperature. We discussed the generalization of EHM to higher dimensions, where our analytic results also apply.

A major open question is the dual geometry for a Fermi gas with finite charge density. The existence of finite fermi momentum makes it inappropriate to use the same EHM mapping defined here, since long wavelength limit is different from low energy limit. A modified tensor network is required in order to describe the correct infrared physics near the Fermi surface.

Appendix A: Correlators for two-band fermionic systems with particle-hole symmetry

Here we derive the detailed results for two-band, particle-hole symmetric models studied in this work. They hold for generic two-band models at arbitrary chemical potential $\mu$, although we will ultimately use them only for the Dirac model at $\mu = 0$.

Due to particle-hole symmetry, the onsite correlator (projector) $C_x$ takes the following form in spin space:

$$C_x = \langle \beta_x \beta_x^\dagger \rangle = \left( \begin{array}{cc} a & iA \\ -iA & a \end{array} \right) \quad (A1)$$

where $a$ and $A$ are real, up to inconsequential corrections at nonzero temperatures. At zero chemical potential $\mu$, we always have $a = \frac{1}{2}$. The single-particle propagator is slightly more complicated:

$$C_{x-y} = \langle \beta_x \beta_y^\dagger \rangle = \left( \begin{array}{cc} b & iu \\ iv & b \end{array} \right) \quad (A2)$$

When $\mu = 0$, the equal-spin propagator $b = 0$ and the unlike-spin propagators $u, v$ are real. At nonzero $\mu$, $u, v$ are not necessarily real but $b$ is still real. $|u| \neq |v|$ in general, since $C_{x-y}$ does not have to be hermitian in spin space alone. When the onsite propagators $C_x = C_y$, as in the case when they are related by translation symmetry in the same bulk layer, we obtain upon substituting Eqs. A1 and A2 into Eq. G2

$$I_{xy} = \frac{\beta \mu}{\gamma^2} \left[ |a| \frac{2b^2}{(A^2 - (1-a)^2) + 2b A(1-2a) Re[u-v]} \right] \quad (A3)$$

$$G_q(\tau) = \frac{e^{-\tau \mu}}{2} \left( \cosh(\tau E_q) \mathbb{1} + \frac{h_q}{E_q} \sinh(\tau E_q) \right) \left( 1 + \frac{\sinh(\beta \mu)}{\cosh(\beta E_q) + \cosh(\beta \mu)} \right) \frac{\mathbb{1}}{E_q} \quad (A6)$$

where $a, A, b, u, v$ are defined in Eqs. A1, A2 and G1. At zero chemical potential, $b = 0$ and $a = \frac{1}{2}$, and Eq. A3 simplifies further to

$$I_{xy}|_{\mu=0} = \frac{4(|u|^2 + |v|^2)}{1 - 4A^2} \quad (A4)$$

Since the onsite contribution $A$ does not vary with the spatial displacement $x - y$, the decay properties of $I_{xy}$ at $\mu = 0$ depends almost entirely on $u$ and $v$.

From Eq. A1, it is almost trivial to write down the expression of the single-site Entanglement entropy (EE):

$$S_x = -Tr(C_x \log C_x + (\mathbb{1} - C_x) \log(\mathbb{1} - C_x))$$

$$= -2 \sum_{\lambda_{\pm}} \left( \lambda_{\pm} \log \lambda_{\pm} + (1 - \lambda_{\pm}) \log(1 - \lambda_{\pm}) \right) \quad (A5)$$

where $\lambda_{\pm} = a \pm |A|$ are the eigenvalues of $C_x$. When $\mu = 0$, $a = \frac{1}{2}$ and the EE is maximal at $S_x^{\max} = \log 4$ at $A = 0$. Indeed, without unequal-spin correlation ($A = 0$), we have no information about what is happening to the other spin state. When $A$ is small, the maximal entropy is corrected according to $S_x \approx S_x^{\max} - 2A^2 \approx \log 4 - 2A^2$. $S_x$ vanishes when $a = A = \frac{1}{2}$, which produces a pure eigenstate $\propto |\uparrow\rangle + |\downarrow\rangle$.

We now present the explicit forms of the correlators, denoted collectively as $G_q$. Given a hamiltonian $h_q$, $G_q(\tau) = e^{\beta h_q(\tau) - \mu} (\mathbb{1} + e^{\beta h_q(\tau) - \mu})^{-1}$ (Eq. 17) is explicitly

$$G_q|_{\mu=0} = \frac{1}{2} \mathbb{1} - \frac{h_q}{2E_q} \tanh \frac{\beta E_q}{2} \quad (A8)$$

Of course, this further reduces to the usual projection operator given by $\frac{1}{2} \left( \mathbb{1} - \frac{h_q}{2E_q} \right)$ at zero-temperature.

Appendix B: Derivation of the bulk mutual information for $(1+1)$-dim critical boundary systems at $T = 0$

We start from the following expression for the mutual information $I_{xy}$ between sites $x$ and $y$ (Eq. A4):

$$I_{xy}(\mu) = \frac{4(|u|^2 + |v|^2)}{1 - 4A^2}$$

Due to particle-hole symmetry, the onsite correlator (projector) $C_x$ takes the following form in spin space:

$$C_x = \langle \beta_x \beta_x^\dagger \rangle = \left( \begin{array}{cc} a & iA \\ -iA & a \end{array} \right) \quad (A1)$$

where $a$ and $A$ are real, up to inconsequential corrections at nonzero temperatures. At zero chemical potential $\mu$, we always have $a = \frac{1}{2}$. The single-particle propagator is slightly more complicated:

$$C_{x-y} = \langle \beta_x \beta_y^\dagger \rangle = \left( \begin{array}{cc} b & iu \\ iv & b \end{array} \right) \quad (A2)$$

When $\mu = 0$, the equal-spin propagator $b = 0$ and the unlike-spin propagators $u, v$ are real. At nonzero $\mu$, $u, v$ are not necessarily real but $b$ is still real. $|u| \neq |v|$ in general, since $C_{x-y}$ does not have to be hermitian in spin space alone. When the onsite propagators $C_x = C_y$, as in the case when they are related by translation symmetry in the same bulk layer, we obtain upon substituting Eqs. A1 and A2 into Eq. G2

$$I_{xy} = \frac{\beta \mu}{\gamma^2} \left[ |a| \frac{2b^2}{(A^2 - (1-a)^2) + 2b A(1-2a) Re[u-v]} \right] \quad (A3)$$

$$G_q(\tau) = \frac{e^{-\tau \mu}}{2} \left( \cosh(\tau E_q) \mathbb{1} + \frac{h_q}{E_q} \sinh(\tau E_q) \right) \left( 1 + \frac{\sinh(\beta \mu)}{\cosh(\beta E_q) + \cosh(\beta \mu)} \right) \frac{\mathbb{1}}{E_q} \quad (A6)$$

where $a, A, b, u, v$ are defined in Eqs. A1, A2 and G1. At zero chemical potential, $b = 0$ and $a = \frac{1}{2}$, and Eq. A3 simplifies further to

$$I_{xy}|_{\mu=0} = \frac{4(|u|^2 + |v|^2)}{1 - 4A^2} \quad (A4)$$

Since the onsite contribution $A$ does not vary with the spatial displacement $x - y$, the decay properties of $I_{xy}$ at $\mu = 0$ depends almost entirely on $u$ and $v$.

From Eq. A1, it is almost trivial to write down the expression of the single-site Entanglement entropy (EE):

$$S_x = -Tr(C_x \log C_x + (\mathbb{1} - C_x) \log(\mathbb{1} - C_x))$$

$$= -2 \sum_{\lambda_{\pm}} \left( \lambda_{\pm} \log \lambda_{\pm} + (1 - \lambda_{\pm}) \log(1 - \lambda_{\pm}) \right) \quad (A5)$$

where $\lambda_{\pm} = a \pm |A|$ are the eigenvalues of $C_x$. When $\mu = 0$, $a = \frac{1}{2}$ and the EE is maximal at $S_x^{\max} = \log 4$ at $A = 0$. Indeed, without unequal-spin correlation ($A = 0$), we have no information about what is happening to the other spin state. When $A$ is small, the maximal entropy is corrected according to $S_x \approx S_x^{\max} - 2A^2 \approx \log 4 - 2A^2$. $S_x$ vanishes when $a = A = \frac{1}{2}$, which produces a pure eigenstate $\propto |\uparrow\rangle + |\downarrow\rangle$.

We now present the explicit forms of the correlators, denoted collectively as $G_q$. Given a hamiltonian $h_q$, $G_q(\tau) = e^{\beta h_q(\tau) - \mu} (\mathbb{1} + e^{\beta h_q(\tau) - \mu})^{-1}$ (Eq. 17) is explicitly

$$G_q|_{\mu=0} = \frac{1}{2} \mathbb{1} - \frac{h_q}{2E_q} \tanh \frac{\beta E_q}{2} \quad (A8)$$

Of course, this further reduces to the usual projection operator given by $\frac{1}{2} \left( \mathbb{1} - \frac{h_q}{2E_q} \right)$ at zero-temperature.
\[ I_{xy}|_{\mu=0} = \frac{4|u|^2 + |v|^2}{1 - 4A^2} \sim 8|u|^2 \sim 8|v|^2 \]  

(B1)

where, as introduced in the main text and the previous appendix, \( u \) and \( v \) are the unlike-spin single particle propagators, and \( A \) the unlike-spin on-site propagator which tends to zero beyond moderately large \( n \). Below, we shall derive their asymptotic behavior in detail.

1. Angular direction

We evaluate Eq. 35 for large a large angular interval of \( \Delta x \) sites by deforming the contour around the branch cut from \( z = 0 \) to \( z = \infty \). (looking like a tight-lipped Pac-man):

\[ u \sim v \sim \frac{1}{2} \int_0^1 W_n^*(z^{-1})W_n(z)z^{2^n - \Delta x}(\sqrt{z} - \sqrt{\epsilon^2 z}) \frac{dz}{z} \]

\[ = \int_0^1 W_n(z^{-1})W_n(z)z^{2^n - \Delta x} \frac{dz}{\sqrt{z}} \]

\[ = \int_0^1 (W_n^*(z^{-1})W_n(z)z^{2^n})z^{2^n(\Delta x - 1) - 1/2} dz \]

\[ = \int_0^1 Q(z)z^X dz \]  

(B2)

where \( W_n(z) = \frac{1}{\sqrt{2\pi}}D(z^{2^n-1})\prod_{j=1}^{n-1} C(z^{j-1}) \) and \( C(z), D(z) = \frac{1 + x}{\sqrt{x}} \). We have decomposed the integrand into a term \( Q(z) = W_n^*(z^{-1})W_n(z)z^{2^n} \) that does not have negative powers of \( z \), and \( z^X \) with \( X = 2^n(\Delta x - 1) - 1/2 \) still very large. We next integrate by parts to get the asymptotic behavior of \( u \) or \( v \):

\[ u \sim v \sim \int_0^1 Q(z)z^X dz \]

\[ = \frac{Q(1)}{X + 1} - \frac{1}{X + 1} \int_0^1 Q'(z)z^{X+1} dz \]

\[ = \frac{Q(1)}{X + 1} - \frac{Q'(1)}{(X + 1)(X + 2)} + ... \]

\[ = 0 - 0 + \frac{Q''(1)}{(X + 1)(X + 2)(X + 3)} + ... \]

\[ \sim \frac{Q''(1)}{X^3} \]  

(B3)

Here, we have stopped at the 2nd derivative of \( Q \), because it is the lowest nonzero derivative at \( z = 1 \). \( Q(1) = Q'(1) = 0 \) because they each must contain at least one factor of \( W_n(1) \) or \( W_n^*(1) \), both of which are zero due to the presence of UV projectors \( D(z^{2^n-1}) \). We also truncate off higher derivative terms as they contain higher powers of \( \frac{1}{X} \). As one may expect, \( u \) or \( v \) depends \textit{exclusively} on the behavior of the EHM basis at \( z = 1 \) or \( q = -i\log z = 0 \), the IR point where criticality occurs.

Substituting the explicit form of \( Q(z) \) and differentiating, we obtain

\[ u \sim v \sim \frac{Q''(1)}{X^3} \]

\[ = \frac{\pi}{2^{2(n-1)}}|C(1)^{n-1}D'(1)|^2 \frac{1}{X^3} \]

\[ = \frac{\pi}{2^{2(n-1)}} \left| \sqrt{2^{n-1}} \left( -\frac{1}{\sqrt{2}} \right) \right|^2 \frac{1}{X^3} \]

\[ = \frac{\pi}{2^{3(n-4)}} \frac{1}{(2^n\Delta x)^3} \]

(B4)

That \( n \) drops out is not a coincidence, but a manifestation of scale invariance. Note that the presence of the critical point, which is a property of the Hamiltonian, only ensures that the first line of Eq. (2) will not evaluate to zero; the power-law decay rate is \textit{entirely} determined by the analytic properties of the chosen EHM basis at that IR point. In this case, the mutual information behaves asymptotically as

\[ I_{xy} = I_n(\Delta x) \sim \frac{1}{32\pi^2} \frac{1}{(\Delta x)^6} \]  

(B5)

2. Radial direction

Here, we evaluate Eq. 36 for the mutual information between sites that are separated radially. When one of the layers lies at the UV boundary of the bulk (layer 1), \( u \) and \( v \) between layers 1 and \( n \) can be easily evaluated viz.

\[ u, v = -i \int_{|z|=1} \frac{dz}{z} W_1^*(z^{-1})W_n(z)z^{\mp \frac{1}{2}} \]

\[ = -i \int_{|z|=1} \frac{dz}{z} 2\pi \sqrt{2^n-1} \frac{1-(1-z^{-1})(1-z^{2^n-1})^2}{1-z} z^{\mp \frac{1}{2}} \]

\[ = i \int_{|z|=1} \frac{dz}{z} \left( 1 - 2z^{2^n-1} + 2z^n \right) \]

\[ = i \int_{|z|=1} \frac{dz}{z^{\mp \frac{1}{2}}} - i \int_{|z|=1} \frac{(2z^{2^n-1} - z^n)dz}{z^{2\pm \frac{1}{2}}} \]  

(B6)

The first integrand diverges when \( z \to 0 \), so the contour should be inverted about \( |z| = 1 \) and closed at infinity. The second one diverges when \( z \to \infty \) for \( n \geq 2 \), so the contour should be closed like a Pac-man.

Performing the resultant real integrals analogously to Eq. (2), we obtain

\[ |u| = \frac{1}{2\pi \sqrt{2^n-1}} \]  

(B7)
The single-particle bulk propagator is not hermitian in spin-space, with \( u \neq v \). The above are exact results, not asymptotic ones. However, exact results like these usually do not exist for more generic wavelet mappings. The resultant mutual information is

\[
I_{xy} = I(1, n) \sim 4(|u|^2 + |v|^2) = \frac{10}{9\pi^2} \frac{1}{2n-1}
\]

(B9)

Appendix C: Calculational details for the bulk mutual information at nonzero temperature for critical systems in arbitrary number of dimensions

In this appendix, we shall fill in the mathematical gaps in the derivations of various nonzero \( T \) results for gapless systems. Since the mutual information \( I_{xy} \) between sites \( x \) and \( y \) is (Eq. A4),

\[
I_{xy} = 4(|u|^2 + |v|^2) \sim 8|u|^2 \sim 8|v|^2
\]

where \( A \) trivially approaches zero beyond the first few layers \( n \), we will just need to find the asymptotic behavior of the unlike-spin single particle propagators (two-point functions) \( u \sim v \).

1. Decay of nonzero \( T \) correlators for generic critical dispersions

We consider the energy dispersion Eq. 99

\[
E_q = \sqrt{\sum_{j=1}^{D} v_j^2 q_j^{2\gamma_j}}
\]

In the \( j^{th} \) direction, the decay rate of the correlators \( u, v \) is given by the the imaginary part of the root \( q = q_j \) of

\[
v_j^2 q_j^{2\gamma_j} = -(m^2 + \pi^2 T^2)
\]

(C2)

nearest to the real axis, where \( m^2 = \sum_{j \neq j}^{D} v_j^2 q_j^{2\gamma_j} \), denotes an effective mass from the momentum contributions from all the other directions. \( m^2 \ll T^2 \) is always satisfied for a bulk layer sufficiently deep in the IR, i.e. of sufficiently large \( n \). In terms of the variable \( z = e^{iq} = e^{i\theta_j} \) or \( q = q_j = \frac{2\pi j}{v} \) used previously, the decay rate is given by \(-\log |z_0|\), where \( z_0 \) is the root of

\[
z^4 + 2(\alpha_j - 1)z^2 + 1 = 0
\]

within the unit circle and closest to its boundary, with \( \alpha_j = \frac{2\pi j}{v} \left((\pi T)^2 + m^2\right)^{1/\gamma_j} \). Solving the above equation and taking the imaginary part,

\[
|\text{Im}(q_j(m))| = \frac{\sin \frac{\pi}{2\gamma_j}}{v_j^{1/\gamma_j}} \left((\pi T)^2 + m^2\right)^{1/(2\gamma_j)}
\]

\[
\approx U_j \left( 1 + V_j \sum_{i \neq j} D \frac{v_i^2 q_i^{2\gamma_i}}{|q_j|} \right)
\]

(C4)

where \( U_j = \sin \frac{\pi}{2\gamma_j} \left( \frac{\pi T}{v} \right)^{1/\gamma_j} \) and \( V_j = (2\gamma_j(\pi T)^2)^{-1} \). However, this is not the physical decay rate as it still depends on the other momenta. To obtain the physical decay rate, we integrate over the latter (taking \( j = 1 \) without loss of generality):

\[
u \sim v \sim \int e^{i2nq \Delta x} \tanh \frac{\beta E_q}{2} dq
\]

\[
\sim \prod_{j=1}^{D} \int dq_j e^{-2n|\text{Im}(q_j(m))|\Delta x_1} e^{i2n \sum_{j \neq 1} D \Delta x_j q_j}
\]

\[
\approx e^{-2nU_1 \Delta x_1} \prod_{j=2}^{D} \int dq_j e^{-U_1 \Delta x_1 q_j^2} e^{i2n \sum_{j \neq j} D \Delta x_j q_j}
\]

\[
\approx e^{-2n\sum_{j=2}^{D} \Delta x_j q_j} e^{-2nU_1 \Delta x_1 \sum_{j \neq 1} D \frac{(\Delta x_j)^2}{v_j}}
\]

(C5)

This is just Eq.105 for the general anisotropic case. For the isotropic linear Dirac case where \( U_j = \frac{\pi T}{v} \) and \( V_j = \frac{1}{2(\pi T)^2} \) for all \( j \), Eq. C5 nicely simplifies to

\[
u \sim v \sim \exp \left(-2n\Delta x_1 \frac{\Delta x_1}{4U_1 \Delta x_1 \sum_{j \neq 1} D \frac{(\Delta x_j)^2}{v_j}}\right)
\]

\[
= \exp \left(-2n\Delta x_1 \frac{\Delta x_1}{4\frac{\pi T}{v} \frac{1}{2(\pi T)^2} \Delta x_1 \sum_{j \neq 1} D \frac{(\Delta x_j)^2}{v_j}}\right)
\]

\[
= e^{-2n \frac{\pi T}{v} \Delta x_1 \left(1 + \frac{\sum_{j \neq 1} D (\Delta x_j)^2}{2\Delta x_1^2}\right)}
\]

\[
\approx e^{-2n \frac{\pi T}{v} \sqrt{\sum_{j \neq 1} D (\Delta x_j)^2}}
\]

(C6)

This shows that the correlators and hence mutual information decay isotropically in \( \Delta x \) for the isotropic linear Dirac model, at least in the neighborhood of \( \epsilon_j = j, j = 1, 2, ..., D \). The nonlinearity of Eq. C5 is further explored in the main text around Fig. 6.
Appendix D: Calculational details for the imaginary time correlator

Here we shall present the full derivations of the more involved results on the imaginary time correlator $C_n(\tau)$. We shall derive the results for an arbitrary chemical potential $\mu$, so as to illustrate the interesting continuous crossover of $C_n(\tau)$ as a nonzero chemical potential is introduced to a critical system.

$$C_n(\tau) = \frac{e^{-\mu \tau}}{2} \int_{-\pi}^{\pi} dq |W_n(e^{iq})|^2 \left[ \theta(E_q - \mu)e^{-\tau E_q} \left(1 - \frac{\hbar_q}{E_q}\right) + \theta(\mu - E_q)e^{\tau E_q} \left(1 + \frac{\hbar_q}{E_q}\right) \right]$$ (D3)

We only have to care about the extreme IR region of this integral, since $e^{-E_q \tau} = e^{-\nu \tau |q| \tau}$ decays rapidly for large $\tau$ in a critical system.

To proceed further, we only need to understand the IR behavior of $W_n(z) = D(z^{n-1}) \prod_{j=1}^{n-1} C(z^{2^{j-1}})$. The chemical potential sets an energy scale that divides two qualitatively different regimes. When the layer $n$ is below the energy scale of $\mu$, i.e. $n < n^*$ where $2^n = \frac{e^{\pi \mu}}{\pi}$, $W_n(e^{iq})$ is effectively dominated by a sharp peak at $q_0 = \frac{2\pi}{\mu} < \mu$. However, for $n > n^*$, $W_n(e^{iq})$ is governed by its analytic behavior near the IR point $z = 1$. Perturbations away from the IR point with $z = e^{i(0+\Delta q)} \approx 1 - i\Delta q$,

$$|W_n(e^{i\Delta q})|^2 \approx |W_n(1 - i\Delta q)|^2 = W_n(1 + i\Delta q)W_n(1 - i\Delta q) \approx \frac{1}{2\pi} \begin{vmatrix} \prod_{j=1}^{n-1} C(1) \end{vmatrix}^2 \left|D'(1)\right|^2 2^{2(n-1)}(\Delta q)^2$$ (D4)

Noting that the even part of $\frac{h_q}{E_q}$ is $\frac{|q|}{2}$, the correlator simplifies to (with $E_\nu = \mu$)

$$C_n(\tau) \approx \frac{e^{-\mu \tau} 2^{3n}}{32\pi} \int_{0}^{\pi} dq q^2 \left[ \theta(q - \nu)e^{-\nu q} \left(1 - \frac{\hbar_q}{q}\sigma_2\right) + \theta(\nu - q)e^{\nu q} \left(1 + \frac{\hbar_q}{q}\sigma_2\right) \right]$$ (D5)

This integral can be exactly solved in terms of incomplete Gamma functions. However, we just want to extract the relevant asymptotic behavior set by the scale $\mu \tau$. Since the correlator captures the IR behavior, it should remain invariant even if the upper limit of $\pi$ is replaced by an arbitrary $q_{\text{cutoff}}$ in the first term on the RHS. The following formulæ come handy: $\int_{0}^{\mu} q^\nu e^{\mu q} dq \sim \frac{\mu^{\nu+1}}{\nu+1}$ for $\mu \ll 1$ and $e^{\mu q} \mu^{\nu+1}$ for $\mu \gg 1$. Also, $\int_{q_{\text{cutoff}}}^{\infty} q^\nu e^{-q} dq \sim \frac{q_{\text{cutoff}}^{\nu+1}}{\nu+1}$ for $\mu \ll 1$ and $e^{-q_{\text{cutoff}}} \mu^{\nu+1}$ for $\mu \gg 1$.

For the case of chemical potential discussed in the main text, $\mu = 0$ and we always have

$$C_n(\tau)|_{\mu=0} \approx \frac{e^{-\mu \tau} 2^{3n}}{16\pi} \frac{1}{v_{F\tau}} \left(1 + \frac{3}{2v_{F\tau}} \sigma_2\right) \bigg|_{\mu=0} \approx \frac{1}{16\pi} \left(\frac{2^n}{v_{F\tau}}\right)^3 \left(1 + \frac{3}{2v_{F\tau}} \sigma_2\right)$$ (D6)

The extension of this result to nonlinear dispersions will be discussed in Appendix E. Eq. D6 may also be used for the short-time behavior when $\mu \neq 0$, as long as $\mu \tau \ll 1$.

Appendix E: Extension to the critical $(1 + 1)$-dim Dirac Model with $M \neq 1$ and general discussion of criticality

In the main text, we have focused on the $M = 1$ case of the critical (gapless) Dirac model

$$H_{\text{Dirac}}(k) = v_F [\sin k \sigma_1 + M(1 - \cos k) \sigma_2]$$ (E1)

where $M$ controls the relative weight between the sin $k$ and $1 - \cos k$ terms. These two terms have respectively linear and quadratic dispersions for small $|k|$, and here we study the effects of their interplay.

A simple plot reveals that the dispersion $E_k = \sqrt{\sin^2 k + M^2(1 - \cos k)^2}$ looks almost perfectly quadratic for $M > 5$. However, the short linear
region near \( k = 0 \) is still expected to dominate the physics at the IR layers of the bulk. To see that this is indeed true, we explicitly calculate the order of the dispersion which is given by the derivative \( \frac{d \log E_k}{dw} \), where \( w = \log k \):

\[
\frac{d \log E_k}{dw} = e^w \left(-M^2 + (-1 + M^2) \cos[w]\right) \cot\left[\frac{w}{2}\right] \quad \frac{-1 - M^2 + (-1 + M^2) \cos[w]}{-1 - M^2 + (-1 + M^2) \cos[w]}
\]

(E2)

For small negative values of \( w = \log k \), \( \frac{d \log E_k}{dw} = 2(1 - M^2 e^{-2w}) = 2 \left(1 - \frac{M^2}{k^2}\right) \approx 2 \). But \( \frac{d \log E_k}{dw} \to 1 \) for large negative \( w \). The transition region occurs at \( k_c \approx \frac{1}{M} \), as shown in Fig. 7. Note that a simple Taylor expansion will not reveal a quadratic dispersion, because it is unable to concentrate on an exponentially small IR region.

![FIG. 7. \( \frac{d \log E_k}{dw} \) for \( M = 2000 \). We see that the dispersion of \( E_k \) is linear (\( \frac{d M}{d w} = 1 \)) for \( w < -\log M \approx -7.6 \) or layer \( n \approx 14 \), but quadratic at momentum above that, till \( k \sim O(1) \) where the dispersion levels off.](image)

The shape of the dispersion discussed above affects the bulk geometry profoundly at nonzero temperature. The emergent black hole radius behaves like \( b \propto T^\frac{1}{2} \), when \( E_k \propto k^7 \). Hence \( M \) sets the critical temperature which separates the \( b \propto T \) and \( b \propto T^\frac{1}{2} \) regimes.

a. Imaginary time correlator

The zero-temperature asymptotics of the imaginary time correlation function are only dependent on the extreme IR behavior of the hamiltonian. As evident in Eq. D3, a very large \( \tau \) in the imaginary time correlator suppresses contributions from all but the lowest energy regime. As such, a finite \( M \) should not change the long time behavior of \( C_n(\tau) \).

This is however not true for an infinite \( M \), which will produce a purely quadratic dispersion since \( k_c \approx \frac{1}{M} = 0 \). Let us write \( E_k = v_0 k^\gamma \) for small \( k \), where \( \gamma = 2 \) here. Then Eq. D5 becomes

\[
Tr C_n(\tau) \approx 2^{3n+1} \frac{\tau}{32\pi} \int_0^\infty \frac{d q^2 e^{-\tau v_0 q^2}}{q^{n+2}}
\]

(E3)

Hence a purely nonlinear dispersion of order \( \gamma \) affects the long time correlator by changing the exponent in the power-law decay from \( 3 \) to \( 3/\gamma \). In our current context with the Dirac model, there exists a moderate imaginary time regime where the correlator decays like \( \sim \frac{1}{\tau^\frac{1}{\gamma}} \). The duration of this regime becomes longer and longer as \( M \) increases, till it finally becomes infinitely long at \( M = \infty \).

b. Spatial correlators and criticality

In general, the power law decay of the spatial correlators depends on the EHM basis, and cannot be changed unless the critical point becomes degenerate. To be precise, the power law decay depends on the existence of a branch cut in the complexified correlator.

In our two-band case, the complexified correlator \( \frac{h^z}{E_k} \), which is introduced in Section IV just before Table I, has nonzero elements given by

\[
\sqrt{i(z - z^{-1}) - iM(2 - (z + z^{-1}))} \quad \sqrt{i(z - z^{-1}) + iM(2 - (z + z^{-1}))}
\]

(E4)

and its reciprocal. They have square-root branch points at \( z = 1, z = \frac{M^2 - 1}{M^2 + 1} \) and \( \frac{M^2 + 1}{M^2 + 1} \). To compute the correlator, we perform the contour integral around \( |z| = 1 \) around the branch cut, from \( z = 1 \) to \( z = \frac{M^2 - 1}{M^2 + 1} \), like what was done in Eq. B2. The correlator matrix elements are thus proportional to

\[
2 \int_1^{\frac{1}{1 + M^2}} W_n^*(z^{-1}) W_n(z) z^{2n} \Delta x \sqrt{F(z)} \frac{dz}{z}
\]

(E5)

where \( F(z) = \frac{\sqrt{(z - 1)(1 + M^2)(z + 1)(1 + M^2)}}{(z - M^2 - 1)(z - 1 + M^2)} \), or its reciprocal. Via the same steps leading to Eq. B3, we will eventually find a \( \sim \frac{1}{\tau^\frac{1}{\gamma}} \) decay in the spatial correlator, as long as the \( z = 1 \) branch point is present.

The branch point at \( z = 1 \) may disappear when it combines with another branch point. In our case, it happens when \( M = \infty \). Then \( F(z) \) becomes trivially equal to unity, and the correlator is identically zero.

There are other more interesting degenerate cases where we end up with a spatial correlator that decays exponentially, even though the system is gapless. This happens when \( F(z) \) has singularities within the unit circle, while the gapless point on the unit circle is not a
branch point. An example is given by

\[ H(k) = \sin^2 k \sigma_1 + (1 - \cos k) \sigma_2 \]  

(E6)

whose singularities in \( z = e^{ik} \) occur at \( |i - 1 + i \sqrt{1 + 2\tau}| = 0.346, 1/0.346 \) and 1, with 1 being a double root that cancels off \( \frac{1}{2\pi} \). Hence its correlator decays like \( \sim 0.346^{2\tau} \).

Physically, the gapless point at \( z = 1 \) is not critical because the two bands touch but do not intersect. The exponential decay arises from the effective mass scale due to the curvature of the dispersion.

For two-band models, gapless points of even order are always noncritical (degenerate). However, such points may be critical if there are more than 2 bands. In general, an \( N \)-band gapless point will be noncritical if the order of its dispersion is a multiple of \( N \).

**Appendix F: Derivation of results for higher-dimensional critical systems at \( T = 0 \)**

1. Decay of the imaginary time correlator for general \( D \)

It is instructive to first perform the derivation for a \((2 + 1)\)-dim boundary system. From Eq. D3, we have

\[ trC_n(\tau) = \int_{-\pi}^\pi \int_{-\pi}^\pi dq_x dq_y |\tilde{W}_n(e^{i q_x})|^2 |\tilde{W}_n(e^{i q_y})|^2 e^{-E_n \tau} \]  

(F1)

where \( \tilde{W}_n \) is the \((1 + 1)\)-dim bulk projector and \( tr \) is a trace over the band indices, not the \( v \) indices (suppressed for now) labeling the \( 2^D - 1 \) bulk sectors containing various combinations of one-dimensional holographic bases. For large \( \tau \), it suffices to consider the contributions close to the IR point \( q = 0 \) where \( W_n(e^{iq}) \) is maximal and \( E_n \approx \sqrt{q_x^2 + q_y^2} \). As explained in the main text, \( \tilde{W}_n(e^{iq}) \) either behaves like a constant or is linear in \( q_j \) near \( q_j = 0 \), depending on whether the IR or UV projector is chosen. In this appendix, we shall derive the forms of all the terms in the correlator \( trC_n^{(1+2)} \), and not just the dominant terms.

Let us write the \( v \) index in binary form \( (v_1, v_2, ..., v_D) \), where \( v_j = 0,1 \) depending on whether the leading factor of \( W_n(z) \) corresponds to an IR or UV projector. From Eq. D4 and the definition of the projectors in the main text, we know that \( |\tilde{W}_n(e^{iq_j})|^2 \approx \zeta_j^2 q_j^{2\kappa_j} \) for \( q_j < \frac{2\pi}{2^\nu} \), where (letting \( \nu_F = 1 \) for simplicity)

\[ \zeta_j^2 = \frac{1}{2\pi} \frac{1}{2^{(-1)\nu_j} + (2\kappa_j + 1)(n-1)} \]  

(F2)

We next perform the integral in Eq. F1 iteratively, starting from the integral over \( q_x \):

\[ trC(\tau) \approx \int_{-\pi}^\pi A_x^2 A_y^2 k^{2\nu} J_{k,\kappa_x}(\tau) dk \]  

(F3)

where \( J_{k,\kappa_x} \) is an effective massive \((1+1)\)-dim correlator. For large \( \tau > \frac{1}{m} \) and \( \kappa_x = 1 \), it can be approximated by

\[ J_{k,\kappa_x=1}(\tau) = \int_{-\pi}^\pi \int_{0}^{\infty} e^{-\sqrt{\frac{k^2 + q^2\tau}{q^{2\kappa}}} dq} \]

\[ \approx 2 \int_{0}^{\infty} e^{-\sqrt{\frac{k^2 + q^2\tau}{q^{2\kappa}}}} dq \]

\[ = 2 \int_{0}^{\infty} e^{-\tau (e^2 - k^2)^{\kappa_x}} \frac{\epsilon}{\sqrt{e^2 - k^2}} d\epsilon \]

\[ = 2 \int_{0}^{\infty} e^{-\tau (e^2 - k^2)^{\kappa_x}} \left( e^2 - \frac{k^2}{2} \right) d\epsilon \]

\[ = e^{-k\tau} \left( e^2 - \frac{k^2}{2} \right)^{\kappa_x} \]  

(F4)

\[ \frac{1}{\tau^3} Q_{\kappa_x=1}(\tau k) \]

where \( Q_{\kappa} \) is a \( 2\kappa \)-th degree polynomial with constant term \((2\kappa)!\). The approximation from line 1 to 2 is extremely accurate for large \( \tau \), while that from line 4 to 5 is valid for extremely small \( k \). This is the regime that contributes most to \( trC_n(\tau) \), because \( J_{k,\kappa_x} \) is suppressed at least like \( e^{-k\tau} \) where \( \tau \) is large. For small \( k \), the integrand does not decay fast, and indeed it is the regime where \( u \gg k \) that contributes most to the integral. The other case, \( J_{k,\kappa_x=0}(\tau) \), resist all known approaches of analytical approximation. However, it is obvious that it behaves asymptotically like

\[ J_{k,\kappa_x=0}(\tau) \sim e^{-k\tau} \]  

(F5)

from the relation \((\partial^2_{\tau} - k^2)J_{k,\kappa_x}=0(\tau) = J_{k,\kappa_x=1}(\tau) \), i.e. with \( Q_{\kappa_x=0}(\tau k) \) \sim const.

For a critical system in \( D + 1 \) dimensions, we just have to replace \( E_q \) by \( \nu_F \sqrt{\sum_{j=1}^{D} q_j^2} \), and substitute that into Eq. F1. Now let’s define \( T_j(\tau) \) to be the integrand of \( trC_n(\tau) \) with the first \( j \) dimensions integrated over. Our goal is to find the asymptotic behavior of \( T_D(\tau) \). We have

\[ T_i(\tau) \approx \prod_{j=1}^{i} \int_{-\pi}^\pi dq_j q_j^{2\kappa_j} \]  

(F6)

where \( P_i = \sqrt{\sum_{j=1}^{i} q_j^2} \). We perform the integral over last variable using the same approximations (valid for large
\[ T_i(\tau) \approx \prod_{j=1}^{i-1} \int_{-\pi}^{\pi} dq_j \zeta_j^2 \int_{-\pi}^{\pi} dq_i \zeta_i^2 e^{-P_i \tau} \]
\[ = 2\zeta_i^2 \prod_{j=1}^{i-1} \int_{-\pi}^{\pi} dq_j \zeta_j^2 Q_j \int_{0}^{\infty} dq_{i} \zeta_i^2 e^{-\sqrt{P_{i-1}^2 + q_{i}^2} \tau} \]
\[ \approx 2\zeta_i^2 \prod_{j=1}^{i-1} \int_{-\pi}^{\pi} dq_j \zeta_j^2 Q_j \sum_{n} \frac{1}{(2\pi)^n} \tau^n \]
\[ = 2\zeta_i^2 \sum_{n} \frac{1}{(2\pi)^n} \tau^n \]

On line 4, the tilde in \( \tilde{Q}_\kappa \) denote normal ordering of the \( \tau \) and \( \frac{d}{d\tau} \) operators, i.e. \( Q_{\kappa j} \) and its products will have all \( \tau \) moved to the left of all \( \frac{d}{d\tau} \). When going from the sixth to seventh line, that note each operator \( (-\tau^n) \frac{d^n}{d\tau^n} \) when acting on expressions of the form \( 1/\tau^{\kappa+1} \), without incurring additional factors of \( 1/\tau \).

Hence
\[ trC_n(\tau) \sim \frac{1}{v_F^3} D \prod_{j=1}^{D} \frac{2(2\kappa_j+1)(n-1)}{(v_F \tau)^{2\kappa_j}} \]

, after restoring \( v_F \). Evidently, the leading terms occur when \( \kappa_j = 1 \) for just one \( j \), and is zero for the others. Hence, we have
\[ TrC_n(\tau) \sim \frac{2^n}{v_F^{3D}} \]

This is the main result for the imaginary time correlator in the multidimensional critical case.

For the multidimensional massive case with a fixed mass \( m \), \( P_i \) in Eq. F7 is replaced by \( P_i = \sqrt{m^2 + \sum_{j=1}^{i} q_j^2} \). Hence \( T_i(\tau) \) also contains a mass and the third last line of Eq. F7 becomes
\[ 2\zeta_i^2 \prod_{j=1}^{i} \tilde{Q}_{\kappa j} \left( -\tau \frac{d}{d\tau} \right) e^{-m\tau} \frac{1}{\tau^{2(\sum_{j=1}^{i} \kappa_j)+1}}, \]

valid for \( m\tau < 1 \) due to the approximations in Eq. F4. Hence
\[ Eq. F8 \]
\[ trC_n(\tau)|_{0 < m\tau < 1} \sim \frac{e^{-m\tau}}{v_F^3} D \prod_{j=1}^{D} \frac{2(2\kappa_j+1)(n-1)}{(v_F \tau)^{2\kappa_j}} + \text{higher orders of } 1/\tau \]

and
\[ trC_n(\tau)|_{m\tau \gg 1} \sim e^{-m\tau} \times \text{weak dependence on powers of } 1/\tau \]

The nonzero mass correlator is exponentially suppressed by \( e^{-m\tau} \), though for small \( m\tau \) we still see a subleading power law in \( \tau \), albeit with a different power from that of the massless case.

2. Nonuniversal properties of (2 + 1)-dim critical model

Here we illustrate how a different choice of model in (2 + 1)-dim can affect certain quantities but not others. We consider the model
\[ H(q_x, q_y) = d(q) \cdot \sigma = \sin q_x \sigma_1 + \sin q_y \sigma_2 + (\cos q_x - \cos q_y) \sigma_3 \]

which is also gapless at \( q = 0 \). Its correlator in momentum space is
\[ G_q = \frac{1}{2} \left( \frac{1}{\pi} \tilde{d}(\sigma) \right) \]

where \( E_q = \sqrt{2(1 - \cos q_x \cos q_y)} \rightarrow \sqrt{q_x^2 + q_y^2} = |q| \) near criticality. When considered as a \( (1 + 1) \)-dim correlator depending on \( q_x(q_y) \) alone, it behaves like a massive correlator with mass \( q_y(q_x) \), as can be seen from its poles at \( \pm i \cosh^{-1} \sec q_y \) (and vice versa for \( q_x \leftrightarrow q_y \)).

Since the single-site correlator \( C_x \) is given by
\[ C_x = \int_{-\pi}^{\pi} d q_x d q_y |W_n(e^{iq_x})|^2 |W_n(e^{iq_y})|^2 G_q \]

where \( |W_n(e^{iq_j})|^2 \) is even about \( q = 0 \), we see that the off-diagonal components, being odd in \( q_x \) or \( q_y \), must disappear. This is different from the \( 1 + 1 \)-dim Dirac model, where \( d_2(q) \), which is not odd in \( q \), plays an important role in the decay of the correlator. In the current \( (2 + 1) \)-dim case, it is \( d_3 \) that controls the decay of the correlator.

Such as importantly, note that the nonconstant part of the diagonal terms are odd under the interchange \( q_x \leftrightarrow q_y \). Hence \( G_q \propto \frac{1}{2} \mathbb{I} \) due to the symmetry between the wavelet bases \( W_n(e^{iq_x}) \) and \( W_n(e^{iq_y}) \). With the
off-diagonal part $A$ (defined previously) vanishing rigorously, the single-site entropy is always maintained at exactly $S_x = \log 4$, the same universal limiting value in the $(1+1)$-dim case. Evidently, the small $n$ (UV) behavior of the entropy depends nonuniversally on the details of the model.

Appendix G: Properties of the Mutual Information

1. Relation to the single-particle correlators

The mutual information as given by Eq. 5 contains the the two-site entanglement entropy, which depends on the two-site correlator $C_{xy}$ via Eq. 9.

It is a matrix of single-particle propagators $[C_{xy}]_{ij} = [\beta_i \beta_j^\dagger]$, where $i,j \in \{x,y\}$ and $\beta_x, \beta_y$ are the bulk annihilation operators. Below, we shall write

$$C_{xy} = \begin{pmatrix} C_x & C_{x-y} \\ C_{y-x} & C_y \end{pmatrix} = C_0 + V \tag{G1}$$

where $C_x$ and $C_y$ the on-site single-particle correlators, and $C_{x-y}$ is the (non-hermitian) single-particle propagator from site $y$ to $x$. The off-diagonal contribution $C_{x-y}$ decays rapidly for large $|x-y|$, and $I_{xy}$ can be accurately approximated in that limit. Below, we write $C_{xy} = C_0 + V$, where $C_0 = C_x \otimes C_y$ and $V$ is a perturbation containing the off-diagonal parts $C_{x-y}$ and $C^\dagger_{x-y}$:

$$I_{xy} = S_x + S_y - S_{xy}$$
$$= S_x + S_y + \text{Tr}((C_0 + V) \log(C_0 + V) + (1 - C_0 - V) \log(1 - C_0 - V))$$
$$\approx S_x + S_y + \text{Tr}((C_0 + V)(\log C_0 + C_0^{-1}V - \frac{1}{2}(C_0^{-1}V)^2)$$
$$+ (1 - C_0 - V)(\log(1 - C_0) + (1 - C_0) - V - \frac{1}{2}((1 - C_0)^{-1}V)^2))$$
$$\approx (S_x + S_y - \text{Tr}(S_x \otimes S_y)) + 2\text{Tr}V + \text{Tr}[V(\log C_0 + \log(1 - C_0))] + \frac{1}{2}\text{Tr}VC_0^{-1}V + \frac{1}{2}\text{Tr}V(1 - C_0)^{-1}V$$
$$= (S_x + S_y - S_x - S_y) + \frac{1}{2}\text{Tr}VC_0^{-1}V + \frac{1}{2}\text{Tr}V(1 - C_0)^{-1}V$$
$$\approx \frac{1}{2}\text{Tr}[V(C_0(1 - C_0))^{-1}V]$$
$$\approx \frac{1}{2}\text{Tr} \left[ \frac{C_{x-y}}{C_x(1 - C_y)} \cdot C_{y-x} + (x \leftrightarrow y) \right]$$
$$\sim \text{Tr}[C^\dagger_{y-x} C_{y-x}] \tag{G2}$$

where $C_x, C_y$ are the single-particle onsite correlators, and $C_{x-y}$ is the single-particle propagator between the two different sites $x$ and $y$. Note that we have implicitly assumed that $C_0$ and $V$ commute while going from lines 2 to 3, which holds in the IR limit.

2. The mutual information in terms of the reduced-density matrix

The mutual information can also be understood as the Kullback-Liebler divergence$^{67}$ of the distributions described by $\rho_{xy}$ and $\rho_{x} \rho_{y}$, where $\rho_{x}$ is the single-site reduced-density matrix (RDM) and $\rho_{xy}$ is the two-site RDM. Writing the trace over one site as $\text{Tr}_x$ and two sites as $\text{Tr}_{xy}$, we have

$$I_{xy} = S_x + S_y - S_{xy}$$
$$= -\text{Tr}_y \rho_{xy} \log \rho_x - \text{Tr}_x \rho_{xy} \log \rho_y + \text{Tr}_{xy} \rho_{xy} \log \rho_{xy}$$
$$= -\text{Tr}_y \rho_{xy} \log \rho_x - \text{Tr}_x \rho_{xy} \log \rho_y + \text{Tr}_{xy} \rho_{xy} \log \rho_{xy}$$
$$= \text{Tr}_{xy} \rho_{xy} \log \frac{\rho_{xy}}{\rho_x \rho_y}$$
$$= \mathbb{E} \left[ \log \frac{\rho_{xy}}{\rho_x \rho_y} \right] \tag{G3}$$

To maximize the mutual information $I_{xy}$, we need $\rho_{xy}$ and $\rho_x \rho_y$ to be as different as possible. Since the log function drops steeply below unity, we especially want to avoid situations where the (square root of the) single-site RDM eigenvalue is large compared to that of the two-site RDM. Since $\rho_x = \text{Tr}_y \rho_{xy}$, the above-mentioned situation is more likely when the RHS contains a large number of contributions from states belonging to different $y$. Hence we conclude that a maximal $I_{xy}$ must have minimal spread of $\rho_{xy}$, i.e. have 2-particle states that
are maximally entangled in the precise sense of Eq. G3. Note that this scenario represents a hypothetical optimum, and may not be realized the physical systems that we have discussed.

Appendix H: Relationship between real and imaginary time correlators

Our discussion of the EHM will not be complete without a proper discussion on the real time correlator, which is arguably of more direct physical significance. However, its oscillatory nature makes it unsuitable as a definition of bulk distance. Here, we shall discuss its mathematical and physical significance with the imaginary time correlator.

1. Critical case with linear dispersion

When there is a linearly dispersive critical point $E_q = v_F q$, Galilean invariance is restored and there is a symmetry between space and time. Restricting ourselves again to $(1+1)$-dimensions, the bulk correlator within a layer is explicitly given by

$$ C(n, n, \Delta x, \Delta t) = \sum_q |W_n(q)|^2 e^{i2\pi q \Delta x} G_q (-i \Delta t) $$

$$ = \sum_q |W_n(q)|^2 e^{i2\pi q \Delta x} e^{iE_q \Delta t} G_q $$

$$ = \sum_q |W_n(q)|^2 e^{i2\pi q \Delta x + v_F \Delta t} G_q $$

which depends symmetrically on $2^n \Delta x$ and $v_F \Delta t$. From Eq. B4, we deduce that the magnitude of the real time correlator behaves like

$$ |C(n, -i \Delta t)| = u|\Delta x = 2^{-n} v_F \Delta t| \sim \frac{1}{16\pi} \left( \frac{2^n}{v_F \Delta t} \right)^3 $$

which is identical to that of the imaginary time correlator. This conclusion is consistent with the result obtained by a naive Wick rotation, since extra factors of $i$ in a power-law do not affect the decay behavior.

When the dispersion is nonlinear, Galilean invariance is lost and the correct result cannot be simply obtained via Wick rotation, even if the system is still critical.

2. Non-critical cases

When a mass scale is present, the energy $E_q$ is bounded below by a value $m$, i.e. $E_q = m + \epsilon_q$ where $\epsilon_q \geq 0$. Hence, the real time bulk correlator

$$ C(n_1, n_2, 0, \Delta t) = \sum_q W_{n_1}^*(q) W_{n_2}(q) e^{iE_q \Delta t} G_q $$

$$ = e^{i\epsilon_q \Delta t} \sum_q W_{n_1}^*(q) W_{n_2}(q) e^{i\epsilon_q \Delta t} G_q $$

acquires an oscillatory phase with frequency $m$, a result again consistent with Wick-rotating the exponential decay $e^{-m\tau}$ behavior of the imaginary time correlator.

Appendix I: The behavior of geodesic distance

Some results of this subsection and the next can also be found in Ref. 30. Here, we reproduce them for completeness.

1. AdS space

Due to its remarkable symmetry, Anti-de-Sitter space can be embedded in a flat Minkowski spacetime one dimension higher. As such, it inherits the simple metric structure of the latter, which yields simple expressions for geodesic distances.

For brevity, let only consider the Euclidean $(2+1)$-dim AdS space, since its higher dimensional analogues will give rise to very similar expressions. We parametrize the space by coordinates $w = (\rho, \theta, \tau)$, and embed it in a 4-d Minkowski spacetime as the locus of $X^{a}x^{b}g_{ab} = X \cdot X = R^2$, where $R$ is the AdS radius, $\eta = \text{diag}(1, -1, -1, -1)$ and

$$ X^{\mu}(w) = \left( \begin{array}{c} \sqrt{\rho^2 + R^2} \cosh \frac{\tau}{\sqrt{R^2 + \frac{L^2}{4\pi^2}}} \\
\sqrt{R^2 + \frac{L^2}{4\pi^2}} \sinh \frac{\tau}{\sqrt{R^2 + \frac{L^2}{4\pi^2}}} \end{array} \right) $$

(H1)

where $\rho$ is a rescaling factor of $\frac{1}{\sqrt{R^2 + \frac{L^2}{4\pi^2}}}$, instead of the more conventional $\frac{1}{R}$. This is to ensure that

$$ X^{a}x^{b}g_{ab} = X \cdot X = R^2 $$

(H2)

(H3)
the rescaled AdS metric
\[
\frac{1 + \frac{\rho^2}{L^2}}{1 + \frac{\rho^2}{L^2}} d\tau^2 + \frac{d\rho^2}{1 + \frac{\rho^2}{L^2}} + \rho^2 d\theta^2 \rightarrow d\tau^2 + \rho^2 d\theta^2
\] (I2)
is $O(2)$-invariant at $\rho = \frac{L}{\tau} \gg R$. From well-known properties of the Minkowski metric, the geodesic distance between points $w_1$ and $w_2$ is given by
\[
d_{12} = R \cosh^{-1} \left( \frac{X(w_1) \cdot X(w_2)}{R^2} \right)
\] (I3)
From Eq. 13, we find the geodesic distance corresponding to an angular displacement to be
\[
d_{\Delta \theta}^\text{min} = R \cosh^{-1} \left( \frac{\rho^2 + R^2 - \rho^2 \cos \Delta \theta}{R^2} \right)
= R \cosh^{-1} \left( 1 + \frac{2\rho^2}{R^2} \sin^2 \frac{\Delta \theta}{2} \right)
\approx 2R \log \frac{\rho \sin \Delta \theta}{R}
\approx 2R \log \frac{\rho \Delta \theta}{R}
\] (I4)
for $\rho \gg R$. In the scale-invariant case where $\Delta x = \rho \Delta \theta$, and we also have $d_{\Delta x}^{\text{min}} \sim 2R \log |\Delta x|$. 

For a radial displacement with $\Delta \rho = |\rho_2 - \rho_1|$, we have
\[
d_{\Delta \rho}^{\text{min}} = R \cosh^{-1} \left( \sqrt{(R^2 + \rho_1^2)(R^2 + \rho_2^2)} - \rho_1 \rho_2 \right)
\approx R \cosh^{-1} \left( \rho_1 \rho_2 R \left( 1 + \frac{R^2}{2\rho_1^2} \right) \left( 1 + \frac{R^2}{2\rho_2^2} \right) - 1 \right)
\approx R \cosh^{-1} \left( \frac{1}{2} \left( \rho_1 + \rho_2 \right) \rho_1 \rho_2 \right)
= R \left| \log \frac{\rho_1}{\rho_2} \right|
= R |\Delta (\log \rho)|,
\] (I5)
also for $\rho_1, \rho_2 \gg R$.

The geodesic distance in the imaginary time direction is given by
\[
d_{\tau} = R \cosh^{-1} \left( \left( \frac{\rho^2}{R^2} + 1 \right) \cosh \frac{2\pi \tau}{L^2 + 4\pi^2 R^2} - \rho^2 \right)
\approx R \cosh^{-1} \left( \frac{\rho^2}{R^2} \left( \cosh \frac{2\pi \tau}{L^2 + 4\pi^2 R^2} - 1 \right) \right)
\approx R \cosh^{-1} \left( \frac{\rho^2}{R^2} \left( \frac{(2\pi)^2 \tau^2}{2(L^2 + 4\pi^2 R^2)} \right) \right)
\sim 2R \log \frac{2\pi \rho \tau}{RL}
\] (I6)
where we have used $\rho \gg R$ while going from line 1 to 2, and $\tau \ll L$ from line 2 to 3 and $\tau r \gg RL$ from line 3 to 4.

2. Geodesics near a blackhole horizon

We start from a metric
\[
ds^2 = V(r)d\tau^2 + \frac{dr^2}{V(r)} + r^2 d\Omega^2
\] (I7)
with $V(r_0) = 0$, which admits a horizon at $r = r_0$. This horizon is a null surface within which $ds^2 = 0$. Intuitively, the geodesics between two points infinitesimally close to the horizon must necessarily wrap around the horizon (i.e. with $r$ being constant), since the cost of radial displacements $\Delta r$ diverges to infinity at the horizon. Hence we always have $\Delta s \approx r_0 \Delta \theta$ near a horizon.

To explore the near-horizon geometry more rigorously, we switch to Rindler coordinates valid near the horizon $r = r_0$. We define
\[
\rho = 2\text{sgn}(r - r_0) \sqrt{\frac{|r - r_0|}{V'(r_0)}}
\] (I8)
so that, to order $O(\rho^2)$, the metric becomes
\[
ds^2|_R = \rho^2 \left( 1 + \frac{V''(r_0)}{8} \rho^2 \right) d\tau^2 + \left( 1 - \frac{V''(r_0)}{8} \rho^2 \right) d\rho^2 + \left( r_0 \pm \frac{|V'(r_0)| \rho^2}{4} \right)^2 d\Omega^2
\] (I9)
where $T = \frac{V'(r_0)}{2} \tau$ and the $\pm$ sign refers to the region immediately outside and inside the horizon respectively.

Upon dropping the 2nd order terms, we recover the usual Rindler metric which just describes a plane with $T$ taking the role of the polar angle. To avoid a conical singularity, we require that $T$ has period $2\pi$, i.e. that the period of $\tau$ and thus $\beta = T^{-1}$ is of the value $V'(r_0)$.

We now specialize to an example most relevant to the main text, which is the near-horizon geometry of a (2+1)-dim BTZ Black hole. The horizon occurs at $r = b$, with another parameter $R$ setting the overall length scale. The horizon must also occur at a $D+1$-th order zero of $V(r)$. Hence we have
\[
V(r) = r^3 - \frac{b^4}{R^2 r}
\] (I10)
with $V'(b) = \frac{3b^2}{R^2}$ and $V''(b) = 0$. That the second derivative is identically zero is unique to $D = 2$ dimensions. After some tedious derivation, the geodesic distance at
Rindler radius $\rho_0$ between two points separated by $\Delta \theta$ is
\[ \Delta \lambda = \sqrt{\frac{2}{3}} \frac{R}{\sqrt{1 + \eta^2}} \cosh^{-1} \left[ \sqrt{1 + \eta^2} \cosh \left( \sqrt{\frac{3}{2}} \frac{\sqrt{1 + \eta^2}}{R} b \Delta \theta \right) \right] \]
where $b$ is the horizon radius and
\[ \eta = \sqrt{\frac{3 \rho_0}{2 R}} \sech \sqrt{\frac{3 b \Delta \theta}{2 R}} \] (I12)
A moment of calculation reveals that the above reduces to
(I11) $\Delta \lambda = b \Delta \theta$ as we approach the horizon where $\eta \propto \rho_0 \to 0$.
