(Received 5 August 2009; published 8 January 2010)

We present the first demonstration of a CNOT gate between two individually addressed neutral atoms. Our implementation of the CNOT uses Rydberg blockade interactions between neutral atoms held in optical traps separated by >8 μm. Using two different gate protocols we measure CNOT fidelities of \( F = 0.73 \) and 0.72 based on truth table probabilities. The gate was used to generate Bell states with fidelity \( F = 0.48 \pm 0.06 \). After correcting for atom loss we obtain an \( a posteriori \) entanglement fidelity of \( F = 0.58 \).

Any unitary operation can be performed on a quantum computer equipped with a complete set of universal gates. A complete set of gates can be comprised of single qubit operations together with a two-qubit controlled-NOT (CNOT) gate [1]. The CNOT gate has been demonstrated in several different physical systems including trapped ions [2,3], superconducting circuits [4,5], and linear optics [6,7]. Numerous proposals exist for neutral atom quantum gates including short range dipolar interactions [8], ground state collisions [9], coupling of atoms to photons [10], magnetic dipole-dipole interactions [11], gates with delocalized qubits [12], and Rydberg state mediated dipolar interactions [13]. Many particle entanglement mediated by collisions has been observed in optical lattice based experiments [14], and a \( \sqrt{\text{SWAP}} \) entangling operation was performed on many pairs of atoms in parallel [15], but a quantum gate between two individually addressed neutral atoms has not previously been demonstrated.

We report here on the demonstration of a two-qubit gate with neutral atoms using Rydberg blockade interactions as proposed in [13]. The Rydberg approach has a number of attractive features: it does not require cooling of the atoms to the ground state of the confining potentials, it can be operated on \( \mu s \) time scales, it does not require precise control of the two-atom interaction strength, and it is not limited to nearest neighbor interactions which is advantageous for scaling to multiqubit systems [16]. Detailed analyses of the Rydberg gate taking into account practical experimental conditions [17,18] predict that gate errors at the level of \( F \sim 10^{-3} \) are possible. We present here initial demonstrations of Rydberg mediated CNOT gates with fidelities based on truth table probabilities of \( F = 0.73 \), 0.72 using two different protocols. The coherence of the gate is shown by measuring coherent oscillations of the output states, with a conditional phase that is dependent on the presence or absence of a two-atom Rydberg interaction. Using superposition input states the gates were used to generate Bell states with fidelity \( F = 0.48 \) which suggests the actual gate fidelity lies between 0.48 and 0.73.

Our implementation of the CNOT gate builds on earlier demonstrations of single qubit rotations using two-photon stimulated Raman pulses [19], coherent excitation of Rydberg states [20], and Rydberg blockade [21,22]. The experimental apparatus and procedures used for excitation of Rydberg states are similar to that described in [21]. As shown there, excitation of a control atom to a Rydberg level with principal quantum number \( n = 90 \) prevents subsequent excitation of a target atom in a neighboring site separated by \( R = 10 \) μm. Excitation and deexcitation of the target atom corresponds to a \( 2\pi \) rotation of an effective spin 1/2 which therefore imparts a \( \pi \) phase shift to the wave function of the target atom. If the control atom blocks the target excitation then the rotation does not occur and there is no phase shift of the target wave function. The result is a \( CZ \) controlled phase operation.

There are several possible ways to convert the Rydberg blockade operation into a full CNOT gate. A standard approach [1] shown in Fig. 1 is to perform Hadamard rotations on the target qubit before and after the controlled phase which immediately generates what we will refer to as a \( H-CZ \) CNOT. An alternative is to implement a controlled amplitude swap (AS-CNOT), as was originally proposed in the context of rare earth doped crystals [23]. As seen in Fig. 1 (right), when the control atom is initially in state \( |0 \rangle \) it is excited to the Rydberg level \( |r \rangle \) by pulse 1 and the blockade interaction prevents Rydberg pulses 2, 4, 6 on the target atom from having any effect. The final pulse 7 returns the control atom to the ground state. When the control atom is initially in state \( |1 \rangle \) pulses 1 and 7 are detuned and have no effect, while pulses 2–6 swap the amplitudes of \( |0 \rangle \) and \( |1 \rangle \). This corresponds to a standard

CNOT apart from a single qubit phase that can be corrected. This approach to generating the CNOT where we have a conditional state transfer, instead of the more usual conditional phase, can be further generalized to efficiently generate many-atom entanglement [24,25].

Our experimental approach shown in Fig. 2 follows that described more fully in [21] and the associated supplementary information. Single $^{87}$Rb atoms are localized in far off resonance traps (FORTs) created by focusing a laser propagating along $+z$ with wavelength $\lambda = 1064$ nm, to spots with waist $(1/e^2$ intensity radius) $w = 3.0 \mu m$. The resulting traps have a potential depth of $U/k_B = 5.1$ mK. The trapped atoms have a measured temperature of $0.08 mK$.

The trapped atoms are localized in far off trapping potentials, apply the CNOT pulses of Fig. 1, and restore the optical traps. Ground state $\pi$ pulses are then applied to either or both atoms to select one of the four possible output states, atoms left in state $|f = 2\rangle$ are removed from the traps with unbalanced radiation pressure (blow away light), and a measurement is made to determine if the selected output state is present.

The time needed to apply the CNOT pulses is about 7 $\mu$s, while the entire cycle time is approximately 1 s. The difference is primarily due to a 0.55 s atom loading phase and the time needed to turn on and off bias magnetic fields which are used during optical pumping and Rydberg excitation. The experiments are performed in a vacuum chamber with a pressure of about $2 \times 10^{-7}$ Pa. Collisions of the trapped atoms with hot background atoms result in a finite lifetime of the trapped atoms with an exponential time constant measured to be about 3 s. We therefore expect a collisional loss during the 0.3 s gap between the first and second measurements of about 10%, which is confirmed by measurements. In addition there is a $\sim 5%$ loss probability due to turning the trapping potential off for 7 $\mu$s. These losses occur independent of the CNOT gate operation and we therefore normalize all two-atom data reported below by a factor of $1/0.85^2$ to compensate for this loss. The reported data were obtained over a period of several months during which the two-atom loss factor varied by no more than $\pm 2%$. We expect that future experiments with better vacuum, colder atoms, and shorter gap time will remove the need for this correction factor.

It is important to emphasize that our use of selection pulses provides a positive identification of all output states and we do not simply assume that a low photoelectron signal corresponds to an atom in $|f = 2\rangle$ before application of the blow away light. This is important because of the nonzero probability of atom loss mentioned above during
each experimental sequence. For example, if we wish to verify the presence of the state $|f = 2, f = 1\rangle$ we apply a $\pi$ selection pulse to the control atom and no selection pulse to the target atom. We then apply blow away light to both atoms and measure if there is still an atom in both sites. A positive signal for both atoms (number of photoelectron counts between the precalibrated single atom and two-atom limits) signals the presence of $|f = 2, f = 1\rangle$. Changing the selection pulses identifies the presence of any of the four possible states.

Following the above procedures we have obtained the CNOT truth tables shown in Fig. 3. For the $H$-C$_Z$ CNOT states $|0(1)\rangle$ are $|f = 1(2), m_f = 0\rangle$ and for the AS-CNOT $|0(1)\rangle$ are $|f = 2(1), m_f = 0\rangle$. In Fig. 3(a) we show the fidelity of our state preparation, which is obtained using the sequence of Fig. 2 but without applying the CNOT pulses. The computational basis states are prepared with an average fidelity of $F = 0.83$. The measured probability matrices for the state preparation and the CNOT gates are

$$U_{\text{prep}} = \begin{pmatrix}
0.77 & 0.04 & 0.01 & 0.0 \\
0.04 & 0.81 & 0.0 & 0.0 \\
0.02 & 0.0 & 0.81 & 0.08 \\
0.00 & 0.07 & 0.04 & 0.93 \\
\end{pmatrix},$$

and

$$U_{\text{CNOT}} = \begin{pmatrix}
0.73 & 0.08 & 0.02 & 0.08 \\
0.00 & 0.72 & 0.02 & 0.03 \\
0.01 & 0.04 & 0.02 & 0.72 \\
0.00 & 0.02 & 0.75 & 0.03 \\
\end{pmatrix}_{AS},$$

$$U_{\text{CNOT}} = \begin{pmatrix}
0.05 & 0.73 & 0.0 & 0.02 \\
0.74 & 0.06 & 0.02 & 0.03 \\
0.02 & 0.02 & 0.79 & 0.06 \\
0.04 & 0.02 & 0.12 & 0.63 \\
\end{pmatrix}_{H-C_Z}.$$

We believe that the finite fidelity of state preparation can be largely attributed to imperfect optical pumping, and small drifts in our preparation and analysis laser pulses. The $H$-$C_Z$ CNOT was obtained using $\pi/2$ pulses that were $\pi$ out of phase which inverts the gate matrix relative to that seen for the AS-CNOT.

The fidelity of transferring the input states to the correct output states is $F = \frac{1}{4} \text{Tr} [U_{\text{ideal}}^\dagger U_{\text{CNOT}}] = 0.73$, 0.72 for the AS and $H$-$C_Z$ CNOT gates. We note that the average ratio of the “high” truth table elements to the “low” elements is about 25:1 which would imply a CNOT fidelity above 0.95. The lower value of the observed fidelity can be attributed to imperfect state preparation, errors in the applied pulses, and a small amount of blockade leakage. The calculated interaction strength [27] for atoms separated by 10.2 $\mu$m along $x$ including the effect of the bias magnetic field, is $B/2\pi = 9.3$ MHz. With a Rydberg excitation Rabi frequency of $\Omega/2\pi = 0.67$ MHz this implies a residual double excitation probability due to imperfect blockade of $P_2 \approx \Omega^2/(2B^2) = 2.6 \times 10^{-3}$. At a temperature of 200 $\mu$K we expect two-atom separations along $z$ extending out to $\Delta z \sim 10$ $\mu$m to occur with $\sim 10\%$ probability. Averaging over the thermal distribution of atomic separations implies a double excitation probability of $P_2 \sim 0.1$. Pulse area and blockade errors imply a nonzero amplitude for either atom to be in a Rydberg state at the end of the gate. In such cases the Rydberg atom is photoionized when the optical trapping potentials are restored which results in atom loss. This is evident in that the average probability sum from each column of Fig. 3 is 0.90 for the state preparation but only 0.82, 0.84 for the CNOT gates.

The intrinsic coherence of the $H$-$C_Z$ CNOT gate is seen in Fig. 3(d) where the output probabilities are shown with a varying gap between pulses 4 and 5 in Fig. 1 for input states $|ct\rangle = |01\rangle$ and $|11\rangle$. Varying the gap time changes the relative phase since our ground state Raman beams are two-photon detuned from the $|1,0\rangle - |2,0\rangle$ transition, to account for the Raman light induced ac Stark shift [19]. The coherent oscillations of the output state curves are $\pi$ out of phase for the control atom in state $|0\rangle$ or $|1\rangle$, corresponding to the conditional $\pi$ phase shift from Rydberg blockade.

The importance of the CNOT gate stems in part from its ability to deterministically create entangled states [28]. To investigate this we used $\pi/2$ pulses on the control atom to prepare the input states $|ct\rangle = \frac{1}{\sqrt{2}} (|0\rangle + i|1\rangle)|0\rangle$ and $|ct\rangle = \frac{1}{\sqrt{2}} (|0\rangle + i|1\rangle)|1\rangle$. Applying the CNOT to these states creates two of the Bell states $|B_1\rangle = \frac{1}{\sqrt{2}} (|00\rangle + i|11\rangle)$ and $|B_2\rangle = \frac{1}{\sqrt{2}} (|01\rangle + |10\rangle)$. The measured probabilities for these output states are shown in Fig. 4.

In order to verify entanglement of the Bell states we measured the parity signal $P = P_{00} + P_{11} - P_{01} - P_{10}$ after applying delayed $\pi/2$ analysis pulses to both atoms.
tanglement of the surviving atom pairs with swapping [31]. A complementary method resulting in entanglement is to use the gate on two pairs of atoms followed by entanglement swapping [31]. Dividing by \( \frac{C_1}{C_2} \), this form of entanglement can be quantified by [29] and the threshold of entanglement for \( F = 0.5 \) is just under the threshold of entanglement of tens of atoms.

FIG. 4 (color online). Measured probabilities for preparation of Bell states \( |B_1\rangle, |B_2\rangle \) using AS-CNOT (left) and \( H-CZ \) CNOT (right). The parity oscillation data were obtained from \( |B_j\rangle \) with the \( H-CZ \) CNOT.

with a variable phase \( \phi \) [28]. A short calculation shows that the parity signal varies as \( P = 2 \text{Re}(C_2) - 2|C_1|\cos(2\phi + \xi) \) where \( C_2 \) is the coherence between states \( |01\rangle \) and \( |10\rangle \), and \( C_1 = |C_1|e^{i\xi} \) is the coherence between states \( |00\rangle \) and \( |11\rangle \). A curve fit yields \( \text{Re}(C_2) = -0.02 \) and \( |C_1| = 0.10 \). The fidelity of entanglement of the Bell state \( |B_j\rangle \) can be quantified by [29] \( F = \frac{1}{4}(P_{00} + P_{11}) + |C_1| \). States with \( 0 < F \leq 1 \) are entangled. The data in Fig. 4 yield \( F = 0.48 \pm 0.06 \) which is just under the threshold of \( F = 0.5 \) for entanglement. The trace of the density matrix for the state \( |B_j\rangle \) in Fig. 4 is \( \text{Tr}[\rho] = 0.83 \) due to atom loss as discussed above. Dividing by \( \text{Tr}[\rho] \) to correct for atom loss implies that the atom pairs which remain after the gate are entangled with fidelity \( F = 0.58 \). This form of \( a \text{ posteriori} \) entanglement [30] is useful for further quantum processing since it could in principle be converted into genuine heralded entanglement by running the gate on two pairs of atoms followed by entanglement swapping [31]. A complementary method resulting in entanglement of the surviving atom pairs with \( F = 0.75 \) has independently been demonstrated by Wilk, et al. [32].
