We introduce a time-dependent Eulerian-Lagrangian length-scale and an inverse locality hypothesis which explain scalings of second order one-particle Lagrangian structure functions observed in Kinematic Simulations (KS) of homogeneous isotropic turbulence. Our KS results are consistent with the physical picture that particle trajectories are more/less autocorrelated if they are smoother/rougher as a result of encountering less/more straining stagnation points, thus leading to enhanced/reduced turbulent diffusion.

I. INTRODUCTION

Turbulent diffusion is a phenomenon of central importance in oceanic, atmospheric, engineering and astrophysical flows. It is known, since the seminal work of Taylor [1], that the turbulent diffusivity (of contaminants, pollutants or other substances advected by the turbulent flow) is proportional to the time-integral of the Lagrangian velocity autocorrelation function \( \langle \delta v^2(\tau) \rangle \) of the turbulence. The Lagrangian study of fluid element trajectories is therefore central to understanding and calculating turbulent diffusion.

A consequence of Taylor’s (1921) [1] theory is that the turbulent diffusivity is larger/smaller depending on whether Lagrangian velocities are correlated over longer/shorter times along trajectories. Such long/short correlation times reflect large/small Lagrangian velocity variations, and Lagrangian velocity variations over a time interval \( \tau \) are characterized by the second order Lagrangian structure function which is proportional to \( 1 - R_L(\tau) \). In statistically stationary and isotropic turbulence it is sufficient to consider only one component of the Lagrangian velocity, say \( v(\tau) \); its second order structure function is \( \langle \delta v^2(\tau) \rangle \equiv \langle (v(t) - v(t + \tau))^2 \rangle \) corresponding to the Lagrangian velocity power spectrum \( E_L(\omega) \) in the frequency (\( \omega \)) domain. As noted by Inoue [2] (see also Tennekes & Lumley [3]), Kolmogorov similarity arguments imply that, in the inertial range of times and frequencies, \( \langle \delta v^2(\tau) \rangle \sim \epsilon \tau \) and \( E_L(\omega) \sim \omega^{-2} \) where \( \epsilon \) is the kinetic energy dissipation rate per unit mass. Support for these scalings has recently been obtained in highly turbulent oceanic environments by Lien et al. [4], in the laboratory by Mordant et al. [5] and in Direct Numerical Simulations (DNS) by Yeung [6]. However, Kolmogorov similarity arguments provide very little understanding of the underlying processes responsible for these scaling laws. What properties of the spatio-temporal flow structure of the turbulence determine that \( \langle \delta v^2(\tau) \rangle \) is proportional to \( \tau \), and what do these properties imply for turbulent diffusion?

In this letter we address this question by use of Kinematic Simulation (KS, see Nicolleau & Vassilicos [7], Davila & Vassilicos [8] and references therein). KS is a Lagrangian model of turbulent diffusion based on kinematically simulated turbulent velocity fields which are incompressible and consistent with up to second order Eulerian statistics of the turbulence such as energy spectra \( E(k) \) in the wavenumber \( (k) \) domain. There is no assumption of Markovianity or delta correlation in time made at any level. Instead, a parameter \( \lambda \) controls the degree of unsteadiness of the turbulence. It might be worth mentioning that, when the energy spectrum input has the Kolmogorov \( k^{-5/3} \) form, KS is in good agreement with laboratory experiments for one-particle statistics [9], two-particle statistics [7], three-particle statistics [10] and concentration variances [11] (particle is used here to mean fluid element). KS is also in good agreement with DNS for two-particle statistics when the KS energy spectrum has the same overall shape as that of the DNS [12]. In this letter, we modify the spatio-temporal flow structure of the KS turbulence by changing the input energy spectrum \( E(k) \) and the input unsteadiness parameter \( \lambda \) and study how \( \langle \delta v^2(\tau) \rangle \) changes as a result.

II. KINEMATIC SIMULATION

In our KS we use 3D turbulent-like velocity fields of the form

\[
\mathbf{u} = \sum_{n=1}^{N_k} \mathbf{A}_n \wedge \hat{\mathbf{k}}_n \cos(\mathbf{k}_n \cdot \mathbf{x} + \omega_n t) + \mathbf{B}_n \wedge \hat{\mathbf{k}}_n \sin(\mathbf{k}_n \cdot \mathbf{x} + \omega_n t) \tag{2.1}
\]

where \( N_k \) (typically of order 100) is the number of modes, \( \hat{\mathbf{k}}_n \) is a random unit vector \( (\mathbf{k}_n = k_n \hat{\mathbf{k}}_n) \), and the directions and orientations of \( \mathbf{A}_n \) and \( \mathbf{B}_n \) are chosen randomly under the constraint that they be normal to \( \mathbf{k}_n \) and uncorrelated with the directions and orientations of all other wave modes. Note that the velocity field (2.1) is incompressible by construction, and also statistically stationary, homogeneous and isotropic as shown by Fung et al. [13] and Fung & Vassilicos [14]. The amplitudes \( A_n \) and \( B_n \) of the vectors \( \mathbf{A}_n \) and \( \mathbf{B}_n \) are determined...
by \( A_n^2 = B_n^2 = \frac{4}{2} E(k_n) \Delta k_n \) where \( E(k) \) is the energy spectrum prescribed to be of the form

\[
E(k) = \frac{v'^2 (p-1)}{2 (L/2\pi)^{p-1}} k^{-p}
\]

(2.2)
in the range \( 2\pi/L = k_1 \leq k \leq k_{N_k} = 2\pi/\eta \) assumed large (i.e. \( L/\eta \gg 1 \)), and \( E(k) = 0 \) otherwise; \( v' \) is the rms of one velocity component of the KS turbulent-like flow; \( \Delta k_n = (k_{n+1} - k_{n-1})/2 \) for \( 2 \leq n \leq N_k - 1 \), \( \Delta k_1 = (k_2 - k_1)/2 \) and \( \Delta k_{N_k} = (k_{N_k} - k_{N_k-1})/2 \). The distribution of wavenumbers is geometric (see [11]), specifically \( k_n = k_1 a^{n-1} \) with a constant \( a \) determined by \( L/\eta = a^{N_k-1} \). The frequencies \( \omega_n \) in (2.1) are proportional to the eddy-turnover frequency of mode \( n \), and the dimensionless constant of proportionality is \( \lambda \), i.e. \( \omega_n = \lambda \sqrt{k_n^3 E(k_n)} \).

![FIG. 1](image1.png)

FIG. 1. The time evolution of the velocity increment \( \langle \delta v^2(\tau) \rangle \) in a log-log plot.

Particle trajectories are numerically integrated in (2.1) and the velocities of the particles are recorded along their flight. By averaging over \( 5 \times 10^3 \) trajectories in \( 5 \times 10^3 \) realizations of the velocity field we obtain \( \langle \delta v^2(\tau) \rangle \) for different values of \( p \) and \( \lambda \) (see Fig. 1 which has been obtained for \( L/\eta = 1600 \), but note that we corroborated these results for much higher values of \( L/\eta \) too). We try values of \( p \) larger than 1 to ensure that the total kinetic energy of the turbulence is finite in the large \( L/\eta \) limit, and values of \( p \) smaller than 2 for the power spectrum \( k^2 E(k) \) of the vorticity and strain rate fields to be an increasing function of \( k \) (see [8]).

III. RESULTS

A first observation is that when \( E(k) \) has the Kolmogorov similarity dependence on wavenumber (i.e. \( p = 5/3 \)), \( \langle \delta v^2(\tau) \rangle \) exhibits the Kolmogorov similarity scaling \( \langle \delta v^2(\tau) \rangle \sim \tau \) over an intermediate range of timescales only for large enough values of \( \lambda \) and not otherwise. This intermediate range of scales turns out to be \( t_\eta \ll \tau \ll T_L \) where \( t_\eta = 2\pi/\omega N_k \). For values of \( \lambda \) smaller than 1 and close to 0 as well as equal to 0, we find \( \langle \delta v^2(\tau) \rangle \sim \tau^{2/3} \) over the intermediate range \( \tau_\eta \ll \tau \ll T_L \) where \( \tau_\eta = 2\pi/\sqrt{(2\pi/\eta) E(2\pi/\eta)} \) and \( T_L \equiv \int_0^\infty R_L(\tau) d\tau \) (\( t_\eta = \tau_\eta/\lambda \)). Fung et al. [13] have already observed this \( 2/3 \) scaling in frozen \( (\lambda = 0) \) KS turbulence and added to (2.1) a sweeping of the small-scales (2.1) by larger small-scales which restored the Kolmogorov similarity scaling \( \langle \delta v^2(\tau) \rangle \sim \tau \). Hence, large values of the unsteadiness parameter \( \lambda \) reproduce this sweeping effect on the scaling of \( \langle \delta v^2(\tau) \rangle \). Kolmogorov similarity is conditional on large values of the dimensionless parameter \( \lambda \), perhaps a surprising result.

![FIG. 2](image2.png)

FIG. 2. Plot of the change in the power law of the Lagrangian velocity increment \( \langle \delta v^2(\tau) \rangle \sim \tau^\alpha \) as a function of \( p \) in KS for different \( \lambda \)'s. The exponent \( \alpha \) and its error bars are calculated from a least square fit over the range of scales where \( \langle \delta v^2(\tau) \rangle \sim \tau^\alpha \) is observed. This power law is harder to detect accurately for values of \( p \) closer to 1 because a larger proportion of the energy is then distributed to higher wavenumbers and both \( \tau_\eta \) and \( t_\eta \) increase indefinitely as \( p \to 1 \) thus requiring an ever larger ratio \( L/\eta \) and therefore value of \( T_L \). The fact that more energy is distributed at the higher wavenumbers when \( p \) decreases means that trajectories are more irregular, a fact reflected in the smaller values of \( \alpha \). With our extremely good time resolutions and ratios \( L/\eta \) up to \( 10^5 \) we still cannot accurately measure values of \( \alpha \) below about 0.4.

Running simulations for a variety of values of \( p \) between 1 and 2 we find

\[
\langle \delta v^2(\tau) \rangle \sim \tau^\alpha
\]

(3.1)
in the intermediate ranges mentioned above and \( \alpha = \alpha(p, \lambda) \) (see figures 1 and 2). For values of \( \lambda \) smaller than 1 including \( \lambda = 0 \),

\[
\alpha = p - 1,
\]

(3.2)
but for values of \( \lambda \) much larger than 1, \( \alpha \) is a monotonically increasing nonlinear function of \( p \), in fact the same function of \( p \) for all large enough \( \lambda \), and is such that
\( \alpha > p - 1 \) and \( \alpha = 1 \) at \( p = 5/3 \). What is this function of \( p \)?

To answer this question we proceed by analogy with Richardson’s locality hypothesis for two-particle diffusion in statistically homogeneous turbulence. According to this hypothesis, the rate of change of the mean square separation between two particles, i.e. \( \frac{d}{dt} \langle \Delta^2 \rangle \), is a function only of \( \langle \Delta^2 \rangle \) and of the variance of Eulerian velocity variations across that length-scale (see [14]). That is

\[
\frac{d}{dt} \langle \Delta^2 \rangle = f \left( \langle \Delta^2 \rangle, \langle \delta u^2(\sqrt{\langle \Delta^2 \rangle}) \rangle \right) \tag{3.3}
\]

where \( \langle \delta u^2(r) \rangle \) is the second order structure function of one component of the Eulerian velocity field. It is well known that \( \langle \delta u^2(r) \rangle \sim r^{p-1} \) for small enough values of \( r \) is equivalent to \( E(k) \sim k^{-p} \) for large enough values of \( k \).

The analogy we are trying here, which we call the inverse locality hypothesis, is to say that the rate of change of \( \langle \delta u^2(\tau) \rangle \) with respect to \( \tau \) is a function only of \( \langle \delta u^2(\tau) \rangle \) and of the length-scale across which the variance of Eulerian velocity variations is equal to \( \langle \delta u^2(\tau) \rangle \). That is

\[
\frac{d}{d\tau} \langle \delta u^2(\tau) \rangle = f \left( \langle \delta u^2(\tau) \rangle, l_e(\tau) \right) \tag{3.4}
\]

where \( l_e(\tau) \) is an Eulerian-Lagrangian length-scale defined as follows:

\[
\langle \delta u^2(l_e(\tau)) \rangle = \langle \delta u^2(\tau) \rangle. \tag{3.5}
\]

We call \( l_e(\tau) \) the equivalent length-scale. Dimensional analysis applied to (3.4) and use of (3.5) and \( \langle \delta u^2(r) \rangle \sim r^{p-1} \) leads to (3.1) with

\[
\alpha = \frac{2(p-1)}{3-p}. \tag{3.6}
\]

This dependence of \( \alpha \) on \( p \) fits surprisingly well the results obtained by KS for large values of \( \lambda \) (see Fig. 2). These results reveal, therefore, the existence of an Eulerian-Lagrangian length-scale \( l_e(\tau) \) which controls the second order Lagrangian structure function and Lagrangian frequency spectrum provided that the sweeping effects are taken into account by high values of \( \lambda \). Our results (figures 1 and 2 and equations (3.2) and (3.6)) also reveal the impact that the two-point spatial flow structure (as reflected in the scaling of the energy spectrum) has on one-particle Lagrangian statistics whether with or without sweeping.

Changes in \( \langle \delta v^2(\tau) \rangle \) imply changes in \( R_L(\tau) \) and therefore in turbulent diffusion. Taylor’s (1921) formula for the mean square one-particle displacement \( \langle x^2(t) \rangle \) is

\[
\frac{d}{dt} \langle x^2(t) \rangle = v^2 \int_0^t R_L(\tau) d\tau \tag{3.7}
\]

which implies a turbulent diffusivity equal to \( v^2 T_L \). Of course this relation remains valid in our KS for any value of \( p \) but the Lagrangian correlation time scale \( T_L \) is found to be an increasing function of \( p \) (see Fig. 3), thus implying a turbulent diffusivity that is also an increasing function of \( p \). This conclusion can be explained qualitatively by the relation \( p + 2D_s/3 = 3 \) between \( p \) and the fractal dimension \( D_s \) of the set of straining stagnation points that has recently been obtained by Davila & Vassilicos [8] for KS turbulence. As \( p \) decreases, \( D_s \) increases implying an increase in the number density of straining stagnation points and thereby an increased probability for particle trajectories to come in the vicinity of such points and experience sudden changes of tack. As a consequence, the Lagrangian correlation time scale is smaller/larger for smaller/larger values of \( p \). In terms of \( D_s \), \( \alpha = \frac{3-D_s}{D_s} \) when \( \lambda \) is large and \( \alpha = \frac{1}{4}(3 - D_s) \) when \( \lambda \) is small; \( \alpha \) is therefore a decreasing function of \( D_s \) thus reflecting the fact that a larger number of changes of tack produces more irregular particle trajectories.

![Figure 3](image)

**FIG. 3.** Plot of Lagrangian correlation time \( T_L \) as a function of \( p \) for \( \lambda = 0.5 \) in KS with \( L/\eta = 100 \). Similar results are found for other values of \( \lambda \) and \( L/\eta \).

### IV. ACKNOWLEDGEMENTS

MAIK and JCV acknowledge support from EPSRC grant GR/K50320, from EC TMR Research network on intermittency in turbulent systems and from the Hong Kong Research Grant Council, China (Project No. HKUST6121/00P). MAIK also wishes to thank the Cambridge Commonwealth Trust, Wolfson College, Cambridge and DAMTP for financial support while this work was being completed. JCV is grateful to the Royal Society of London for its unflinching support over the past eight years.
