Specific DNA duplex formation at an artificial lipid bilayer: fluorescence microscopy after Sybr Green I staining

Emma Werz¹,² and Helmut Rosemeyer*¹

Abstract
The article describes the immobilization of different probe oligonucleotides (4, 7, 10) carrying each a racemic mixture of 2,3-bis(hexadecyloxy)propan-1-ol (1a) at the 5’-terminus on a stable artificial lipid bilayer composed of 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphoethanolamine (POPE) and 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine (POPC). The bilayer separates two compartments (cis/trans channel) of an optical transparent microfluidic sample carrier with perfusion capabilities. Injection of unlabeled target DNA sequences (6, 8, or 9), differing in sequence and length, leads in the case of complementarity to the formation of stable DNA duplexes at the bilayer surface. This could be verified by Sybr Green I double strand staining, followed by incubation periods and thorough perfusions, and was visualized by single molecule fluorescence spectroscopy and microscopy. The different bilayer-immobilized complexes consisting of various DNA duplexes and the fluorescent dye were studied with respect to the kinetics of their formation as well as to their stability against perfusion.

Introduction
The post-biosynthetic lipophilization of various biomolecules such as of proteins and carbohydrates is of decisive importance for the correct function of the cell [1]. With the recent discovery of geranylated tRNAs in bacteria [2] the interest in so-called lipo-oligonucleotides (LONs) has grown tremendously [3,4]. The ability to form complex nano-architectures [5,6] as well as self-assembling aggregates such as micelles, vesicles [3] and bilayer formation of nucleolipids [7] offers numerous possibilities, e.g., for drug delivery [3]. Simultaneously, the interaction of such nanostructures with lipid membranes becomes an ever-greater focus [5,6,8-11].

The study of the interactions of single- and double-stranded nucleic acids with lipid bilayers is, therefore, of significant importance, particularly for the following reasons: 1. for the optimization of the in vivo delivery of lipophilic siRNAs [12-14],...
2. for the development of analytical techniques for the detection of nucleic acids [15-17], 3. for structure elucidation of complex aggregates formed by such natural nanostructures [5,6] and 4. for cell-surface engineering [18].

In a preceding manuscript [19] we reported the lipid bilayer immobilization of lipo-oligonucleotides carrying a racemic bis(hexadecyloxy)propan-1-yl tag (1a) at the 5’-termini at an artificial lipid bilayer–water phase boundary. These were prepared using the cyanoethyl phosphoramidite 1b. A specific duplex formation with complementary cyanine-5 (Cy5)-labelled DNA strands (2b) – prepared by using compound 2a – was proven by fluorescence microscopy. Now, we simplify this technique by hybridizing an unlabelled DNA target strand to the bilayer-immobilized lipo-oligonucleotide and by using Sybr Green I (3, SG) [20-22] as a fluorescent double strand indicator [20-22]. This bears the advantage that the target DNA – the presence or absence of which is going to be analysed – should not be labelled separately with a fluorochrome tag such as cyanine-5 (Cy5) or TAMRA, neither by chemical synthesis nor by a polymerase chain reaction (PCR).

The chemical formulae (1–3) as well as the lipo-oligonucleotide sequences the paper is dealing with are shown in Figure 1.

Results and Discussion

Figure 2 displays the six DNA duplexes which have been assembled at the artificial lipid bilayer and visualized by addition of Sybr Green I.

In the following the results of these experiments regarding the kinetics of incorporation into the bilayer (or its formation) as well as the release of the ternary complex (or its disaggregation) upon perfusion of the cis channel is described. Figure 3 illustrates a scheme of the experimental setup (for details see Experimental).

Experiment A: 4 + 5 + SG. In a preceding manuscript we have studied the bilayer incorporation of the lipo-oligonucleotide 4 (5’-d(1a-TAG GTC AAT ACT)-3’) and its successful and specific duplex formation with the cyanine-5-labeled complementary strand 5 (5’-d(Cy5)-p-AGT ATT GAC CTA)-3’) [19].
As a negative control it had been shown that a membrane-bound duplex formation between the lipo-oligonucleotide 7 (5'-d(1a-ATC CAG TTA TGA)-3') and the oligomer 5 failed. Now, we repeated the first experiment (4 + 5) successfully and run a z-scan of the bilayer after 45 min of incubation with a laser irradiation of the Cy5 dye at 635 nm (Figure 2).

Then, a Sybr Green I (3) solution in dimethyl sulfoxide (≈1 µg/mL) was added to the cis compartment of the slide. In the first experiment (A) laser irradiation of the intercalated dye was performed at 470 nm. In orienting experiments Sybr Green I was irradiated at 470 nm, in order to see if this dye stains the complementary DNA strands 4 + 5, which are known to form a duplex at the bilayer membrane [19]. Firstly, we evaluated the optimal measuring conditions such as the volume, the Sybr Green I concentration as well as of the lipo-oligonucleotides. At this point we first wanted to find out if a non-optimal wavelength of 470 nm would be sufficient for an efficient irradiation of the dye. It turned out, however, that an irradiation of Sybr Green I needs an irradiation wavelength which meets the optimal absorption wavelength to a higher extent. In subsequently performed experiments (B to F) the intercalated Sybr Green I was irradiated at 488 nm because this wavelength is close to its absorption maximum at 494 nm [20-22]. The experiments confirmed a duplex formation in an antiparallel mode on the bilayer surface being stable towards perfusion (Figure 4).

Figure 5 demonstrates the difference in the bilayer brightness upon irradiation of either cyanine-5 (635 nm) [19] or of the ternary complex with SG (4 + 5 + SG) (470 nm). For the determination of the bilayer brightness a region-of-interest (ROI) was defined around the bilayer, and subsequently the density of the intensity counts were summarized (for details, see Experimental).

Besides the bilayer brightness, also the diffusion time, $t_D$, of the lipo-oligonucleotide duplex–Sybr Green I complex (i) within the bilayer (location 1) and (ii) above the bilayer (location 2) was determined (Figure 6).

Table 1 and Table 2 summarize the diffusion times [$t_D$ (ms)] of the complexes 4·5·SG and 4·6·SG before and after a perfusion at the two locations 1 and 2 as illustrated in Figure 6. It can be clearly seen that the diffusion time of the aggregates is significantly longer within the bilayer compared to the region slightly above (location 2), proving the strong immobilization of the lipophilized DNA duplex within the bilayer via the lipophilic head group. The fastest diffusion of the aggregates occurs in free solution without bilayer (Table 2) [19].

Experiment B: 4 + 6 + SG and control experiment: 7 + 6 + SG. In a second series of experiments we used an unlabelled target DNA (6) for duplex formation at the lipid bilayer and added
Table 1: Diffusion times $t_D$ (ms) of the 4·5·SG complex in the presence of a lipid bilayer, either by irradiation of the cyanine-5 dye or by irradiation of intercalated Sybr Green I within the 4·5·SG complex, before and after perfusion of the cis compartment. Location 1: bilayer; location 2: solution in close proximity to the bilayer (Figure 6).

| Sample | Cy5 – irradiation (635 nm) | 4·5·SG complex | SG – irradiation (470 nm) |
|--------|---------------------------|----------------|-------------------------|

| | 17.23 ± 2.0$a$ | 10.33 ± 2.0 | 0.60 ± 0.09 | 1.20 ± 0.36 |
| | 2.47 ± 0.3$a$ | 1.28 ± 0.05 | 0.72 ± 0.11 | 0.13 ± 0.05 |

$a$Data were taken from [19].

Figure 3: Experimental setup. Schematic drawing of the laser scanning microscope, the optical transparent microfluidic bilayer slide, and the lipid bilayer with the incorporated double-tailed lipo-oligonucleotides as well as of Sybr Green I, forming a membrane-bound nucleic acid duplex–dye complex.

Figure 4: Chronological protocol of duplex formation of the lipo-oligonucleotide 4 with the complementary Cy5-labelled target strand 5 with simultaneous staining of the DNA duplex with Sybr Green I. A) Z-Scan of an empty bilayer; after the bilayer has been formed, both compartments (cis and trans) were perfused for 30 s (1.1 mL/min, each). Cy5 irradiation at 635 nm. The z-scan as in (A) with a Sybr Green I irradiation at 470 nm is not shown. As demonstrated in (A) there is no fluorescence in the bilayer. B) Z-Scan after addition of the oligomer 4 (8 µL, 500 nM) to the cis compartment, followed by 45 min of incubation, Cy5 irradiation at 635 nm. C) Z-Scan after addition of the oligomer 5 (8 µL, 50 nM) to the cis compartment and 45 min of incubation; Cy5 irradiation at 635 nm. D) Z-Scan after addition of Sybr Green I (8 µL, 500 nM), followed by 45 min of incubation; Cy5 irradiation at 635 nm. E) Z-Scan as in (D), but with Sybr Green I irradiation at 470 nm. F) Z-Scan after an incubation of 5 min and Sybr Green I irradiation at 470 nm. G) Z-Scan after 30 s of perfusion of the cis compartment (1.1 mL/min) and Sybr Green I irradiation at 635 nm. H) Z-Scan as in (G), but with Sybr Green I irradiation at 470 nm.

only a DMSO solution of Sybr Green I to the cis compartment of the bilayer slide. As can be seen from Figure 7 also the hybridization of an unlabelled target oligomer 6 with the lipo-oligonucleotide 4 can be proved by adding the dye and irradiation at 488 nm. In case of the incorporation of the lipo-oligonucleotide 7 into the bilayer and addition of the non-
complementary unlabelled oligomer 6 (negative control experiment), no duplex formation occurs (data not shown).

From Figure 7 it can be seen that a stepwise mixing of the lipo-oligonucleotide 4 and the complementary strand 6 with an inter-

Table 2: Diffusion times \( t_D \) (ms) of the 4-6-SG complex in the presence of a lipid bilayer in free solution without bilayer as well as in the presence of a bilayer after 1. and 2. perfusion of the cis compart-
ment. Location 1: bilayer; location 2: solution in close proximity to the bilayer (Figure 6).

| 2. perfusion          | 0.07 ± 0.03    |
Figure 7: Experiment B (4 + 6 + SG). Bilayer brightness as function of the various events (addition of oligonucleotides, addition of Sybr Green I, perfusion number as well as of time [min]) within one graph.

(≈15.2 × 10⁴ kHz). In the following 7 perfusion steps (see Experimental), interrupted by several incubation periods over a period of about 2 h, led to an almost total decrease of the brightness dropping to about 5%. This decrease might be due to either a release of the dye from the intact duplex or to a full disintegration of the ternary complex (4 + 6 + SG).

Experiment C: 4 + 8 + SG. In this experiment the lipo-oligonucleotide 4 is inserted into the lipid bilayer, followed by a dodecamer (8) which matches the sequence of 4 only in its innermost part to 50%. An addition of Sybr Green I does not lead to a fluorescent bilayer indicating an unstable ternary complex at room temperature. This is in contrast to the experiment B where a 100% match of both dodecamers exists.

Experiment D: 4 + 9 + SG. In a further series of experiments we studied the duplex formation of the lipo-oligonucleotide 4 and the oligomer 9 at the lipid bilayer–water phase boundary layer. The oligomer 9 matches 4 to 100% within its innermost part but contains hexameric overhangs at both termini. Duplex formation was again indicated using Sybr Green I.

In this case an interesting phenomenon was observed: after immobilization of oligomer 4 within the bilayer and after addition of the complementary strand 9 30 min later as well as of Sybr Green I, further 30 min later, a full development of maximal fluorescence (normalized maximal brightness of 100% ≈ 5.6 × 10⁴ kHz) of the bilayer could only be observed after ≈1 h (Figure 8). This time of formation of the ternary complex is significantly slower than in the experiments with blunt-ended duplex formation reactions described before, which show an almost spontaneous complex formation with the intercalating dye. Moreover, the complex between 4 and 9 as well as of Sybr Green I at the bilayer seems to be highly labile because already a single perfusion step of the cis compartment (1 min, 1.1 mL of buffer at t = 143 min) leads to an almost 90% disappearance of the fluorescence. Interestingly, however, is the finding that a renewed addition of a Sybr Green I solution to the cis compartment (at t = 168 min) leads again to the appearance of fluorescence 40 min later (brightness, 70%), indicating a partial reconstruction of the complex consisting of 4, 9, and the intercalating dye.

The results described above offer several possibilities of interpretation: The target strand 9 carries 3’-terminally to the recognition site of the lipo-oligonucleotide 4 an overhang of 6 nucleotides in length. Therefore, duplex formation between 4 and 9 over a full length of 12 base pairs leads inevitably to a
clash of the overhang with the bilayer surface. As the head groups of the neighbouring bilayer molecules (POPC, POPE) are both positively charged and the internucleotide residues of the overhanging oligonucleotide are negatively charged, a strong Coulomb attraction should exist which can only be shielded by solvation of the lipid head groups and of the nucleic acid phosphodiester groups as well as by the metal cations of the surrounding buffer. The supramolecular assembly of all reaction partners might look like as shown in Figure 9. From this figure it can be deduced that two different tilt angles ($\theta_1$ and $\theta_2$) probably exist between the bilayer surface and the double helical part ($\theta_1$) as well as between the single stranded sequence and the surface ($\theta_2$). A stretched-out, parallel association of the full length nucleic acid with the bilayer surface can be most probably ruled out. In such case a conformational constraint would arise between the lipid head group and the appending oligonucleotide. Moreover, a Cy-5-labelled oligonucleotide such as compound 5 should be bound tightly to the bilayer surface leading to a strong and stable fluorescence of the bilayer which could not be observed.

It is, however, obvious that a severe disturbance of either the complex formation between the probe lipo-oligonucleotide 4 and the target nucleic acid 9 and/or the intercalation of the Sybr Green dye by the overhang take place. This might be the reason for the instability of the assembled complex at the lipid bilayer.
Experiment E: 10 + 6 + SG as well as in a reversed order of addition (SG + 10 + 6). Next, the oligomer 10 was prepared which contains the lipophilic 5’ head group 1a and the recognition sequence separated by an oligonucleotide spacer having the same length as the target sequence overhang (6 bp).

From Figure 10 it can be seen that in this case the ternary complex formation occurs spontaneously upon addition of a first portion of the dye solution. This is, however, not a stable situation because an incubation of only 6 min (without perfusion!) leads to a reduction of the bilayer brightness of just 20%. Several further waiting periods, interrupted by 6 perfusions, reduced the bilayer brightness from the original 100% (100% normalized, \( \approx 6.6 \times 10^5 \) kHz) to less than 5% within 2.5 h. A further addition of Sybr Green I at \( t = 212 \) min, however, enhances the bilayer brightness again to about 20%, indicating the presence of a substantial amount of the intact DNA duplex at the lipid bilayer surface on the cis side. Subsequent incubation periods, followed by single perfusion steps reduced the bilayer brightness each time to about 5%. A repeated Sybr Green I addition at \( t = 234 \) min leads again to an enhancement of the brightness value of 18%. A 4th addition of Sybr Green I at 251 min results in an only very slight brightness enhancement of \( \approx 5\% \) (Figure 11).

In Figure 12 the z-scans of the Experiment E – before and directly after Sybr Green I additions – are displayed. As already shown in Figure 10 and Figure 11 the bilayer brightness increases with each Sybr Green I addition. After 6 perfusions and incubation steps the brightness is reduced to almost zero \( (t = 211 \) min), however, with the next additions of the dye the brightness increases again. Only after seven perfusion and incubation periods the brightness does no longer increase significantly, which might be traced back to the fact that the immobilized DNA duplex is meanwhile dissociated, and that the non-lipophilized strand is has been washed out.

In a further experiment using the lipo-oligonucleotide 10 we changed the order of the addition of the three components of the ternary complex to the cis compartment of the bilayer slide (Figure 13). Within the first 11 min we studied the interaction between Sybr Green I and the empty bilayer. As can be seen no ponderable brightness of the bilayer could be detected after addition of the dye. However, after addition of the 24-mer 10 (at

![Figure 10](image_url)

**Figure 10:** Experiment E (10 + 6 + SG). Bilayer brightness as a function of time as well as of various events [addition of the lipo-oligonucleotide 10 (at \( t = 3 \) min); addition of the oligomer 6 (at \( t = 37 \) min); addition of Sybr Green I (at \( t = 70 \) min, 212 min, 234 min, and 251 min); incubation periods, perfusions].
t = 13 min) the brightness increased to about 60% (normalized brightness, 100% ≈6.5 × 10^4 kHz) and stays almost constant (35–50%) until t = 28 min indicating a strong interaction between the dye and the single stranded 24-mer 10 [20]. Such an interaction could not be observed between the dye and the duplex of the 12-mers 4 and 7. A subsequent perfusion reduces the brightness significantly to 5%. Interestingly, a subsequent waiting period of 10 min leads again to an increase of the bilayer brightness back to about 25%. This is probably due to an additional delivery of the complex 10·SG from the cis compartment or from the cis side of the hydrophobic Teflon-made annulus into the lipid bilayer.

At t = 63 min a second portion of the dye solution and at t = 73 min the oligomer 6, being partly complementary to the lipo-oligonucleotide 10, were added. Within an incubation time of 22 min after addition of 6 the full bilayer brightness (100 % at t = 95 min) was reached. Subsequent perfusion steps (1–4) interrupted by several incubation periods reduced the bilayer brightness from 100 to 10% (Figure 14). These results clearly
indicate a significantly higher stability of the ternary complex at the bilayer compared to the complex of experiment D.

Experiment F: \((10 + 9 + SG)\). In the following the lipo-oligonucleotide 10 (24-mer) was immobilized on the lipid bilayer. After an incubation time of 30 min, an equimolar amount of the oligomer 9 – an oligomer of the same length and a central recognition sequence of 12 bases – was added, followed by addition of Sybr Green I after a further waiting period (30 min). Figure 15 displays the full protocol of mean brightness values (both, in % and kHz) as a function of time or the various events (incubation periods or perfusion). After the addition of the dye as last component of the ternary complex at \(t = 66\) min, a maximal brightness is slowly developed within about 2 h. In this case, however, the maximal brightness (normalized 100% \(\approx 6 \times 10^4\) kHz) does not reach the value which had been observed in the experiments A, B, and E. Only in case of experiment D the maximal brightness is even lower than in case F \((2.5 \times 10^4\) kHz).

18 Subsequent perfusions, interrupted by waiting periods of 10 min each, gave after 382 min a bilayer brightness of \(\approx 5\% \approx 1 \times 10^4\) kHz. This indicates that the formation of the ternary complex \(10 \cdot 9 \cdot SG\) occurs slowly, but when it is once formed, it remains stable for more than 6 h.

Conclusion

Figure 16 shows a comparison of the kinetics of complex formation at the lipid bilayer surface for 5 experiments within the first 60 min (brightness [kHz] vs time [min]).

As can be seen, the fastest ternary complex formation occurs for \(10 + 6 + SG\) (Experiment E) where the complex formation occurs at a distance of a hexamer spacer between the bilayer surface and the DNA duplex region with intercalated Sybr Green I. It can also be observed that, in this case, a maximal brightness at \(\approx 6.5 \times 10^5\) kHz is reached.

If the spacer is missing, the complex \((4 + 6 + SG,\) Experiment B) formation occurs significantly slower; the maximal brightness is reached at \(1.5 \times 10^5\) kHz. The same results are found in case of experiment A \((4 + 5 + SG)\) with two different fluorescent dyes – intercalating Sybr Green I and pending cyanine-5 (Figure 5).

For the scenario of experiment F (Figure 2) the complex formation kinetics drops even further, but the brightness reaches a plateau at \(\approx 2 \times 10^5\) kHz. The by far slowest complex formation is observed in case of experiment D (Figure 1) in which a steric clash between the ternary complex and the bilayer surface occurs. Here, no plateau value of the bilayer brightness is reached, and the complex proved to be highly labile.

Further control experiments such as 1. \(6 + 7\) (non-complementary strands + SG); 2. \(5 + 7\) (non-complementary strands) + SG; 3. \(6\) (lipophilized 12-mer) + SG; 4. empty bilayer + SG do not result in fluorescent bilayers. However, addition of Sybr Green I followed by the 18-mer \(10\) (or in the reversed order) to the \(cis\) chamber of the bilayer slide gives almost spontaneously a fluorescent bilayer with brightness values of \(\approx 5 \times 10^4\) kHz.

Further experiments concerning a multiple compartment chamber with a common aqueous sub-phase, as well as a thermostated device for a suppression of nonspecific base pairing are underway [15]. Moreover, ab initio molecular-dynamics- (AIMD)- and ab initio Monte-Carlo- (AIMC)- calculations of
lipid–nucleic acid complexes with MC and MD simulations of semi-quantitative, “course-grained” models (CGM) are going to be performed (Prof. Dr. Philipp Maass, Department of Statistical Physics, University of Osnabrück).

Studies described in this manuscript as well as of those of a forthcoming paper which deals with the interaction of a defined oligonucleotide single strand, carrying nucleolipid head groups of different lipophilicity with lipid bilayer membranes, might be of importance for the optimization of the in vivo delivery of lipophilic siRNA [13] (e.g., by DNA trafficking as shown in Figure 17), as well as of lipid derivatives of nucleoside antimetabolites [23,24]. Moreover, studies of a transdermal application of lipo-oligonucleotides through the human Stratum corneum by iontophoresis techniques are underway.

### Experimental

**Materials**
1-Palmitoyl-2-oleyl-sn-glycero-3-phosphoethanolamine (POPE) and 1-palmitoyl-2-oleyl-sn-glycero-3-phosphocholine (POPC) were purchased from Avanti Polar Lipids (Alabaster, Al), n-decane from Alfa Aesar (Karlsruhe, Germany), dimethyl sulfoxide (DMSO), potassium chloride (KCl), 3-morpholino-
Figure 15: Bilayer brightness as a function of perfusion number and incubation periods for the experiment F (SG + 10 + 6).

Figure 16: Kinetics of the tertiary complex formations of various lipo-DNA/DNA with Sybr Green I during incubation time \(t\) [min] after addition of the dye at \(t_0\) until the first perfusion.

Figure 17: Trafficking of a siRNA by a lipophilized DNA.

propane-1-sulfonic acid (MOPS) and 2-amino-2-hydroxy-methylpropane-1,3-diol (TRIS) were purchased from Roth (Karlsruhe, Germany).

All oligonucleotides 4–10 (Figure 1) were synthesized, purified and characterized by MALDI–TOF mass spectrometry by Eurogentec SA (Liege, Belgium). In each case the detected mass confirmed the corresponding calculated mass. MALDI–TOF–MS \((m/z)\): 4247.7 (4, [M + H]+; calcd 4247.4); 4178.4 (5, [M + H]+; calcd 4178.1); 3645.5 (6, [M + H]+; calcd 3644.5); 4248.1 (7, [M + H]+; calcd 4247.4); 3643.2 (8, [M + H]+; calcd 3644.46); 7306.4 (9, [M + H]+; calcd 7312.9); 6076.4 (10, [M + H]+; calcd 6077.6).

4 5’-d(1a-p-TAG GTC AAT ACT)-3’

5 5’-d[(Cy5)-p-AGT ATT GAC CTA]-3’

6 5’-d(AGT ATT GAC CTA)-3’

7 5’-d(1a-p-ATC CAG TTA GAC)-3’
We have chosen the particular sequences 5’-d(TAG GTC AAT ACT)-3’ and 3’-d(AGC CTA TTA TGA)-5’, because they do neither form hair pins nor self-complementary duplexes. The lipophilized strand and the complementary oligomer contain the same number of all canonical nucleotides, so that a mixture of 1 $A_{260}$ units, each of both strands gives an equimolar mixture. For nearly all base pairs nearly all nearest neighbour combinations exist. Both strands have the same composition; the unmodified duplex exhibits a melting point of 46 °C in a phosphate buffer solution.

A solution of Sybr Green I in DMSO with undisclosed concentration was purchased from Applichem (Darmstadt, Germany) and used as delivered. The concentration of the dye solution ($\approx$1 µg/mL) was measured UV–vis spectrophotometrically using the published extinction coefficient of Sybr Green I at $\lambda_{max}$ of 494 nm (73.000 M$^{-1}$cm$^{-1}$) [20,21].

**Methods**

**General.** A double-beam spectrophotometer (Specord 205, Analytik Jena GmbH, Jena, Germany) was used for spectrophotometric measurements. The UV–vis absorption spectra were carried out using ultra-micro quartz cuvettes type 105.202-QS from Hellma Analytics (Müllheim, Germany).

**Bilayer fabrication and incorporation of lipo-oligonucleotides therein.** Similar as described in [19], in the following the automated bilayer fabrication is described. Horizontal bilayers were fabricated automatically using a lipid mixture of 1-palmitoyl-2-oleyl-sn-glycero-3-phosphoethanolamine (POPE) and 1-palmitoyl-2-oleyl-sn-glycero-3-phosphocholine (POPC) (8:2, w/w, 10 mg/mL of n-decane) within the “Bilayer Slides” (Figure 18C,D) and an add-on for the inverted confocal microscope (Bilayer Slides and Ionovation Explorer, Ionovation GmbH, Osnabrück, Germany). After pre-filling with buffer (250 mM KCl, 10 mM MOPS/Tris, pH 7), the slide was inserted into the stage unit mounted on an inverted confocal microscope (Figure 18A). Ag/AgCl electrodes were mounted and after the addition of 0.2 µL of POPE/POPC lipid to the cis compartment using a 1 µL bended Hamilton syringe (CH-Bonaduz) (Figure 18E), the automated bilayer production was started; a modified painting technique, in which the air-water interface paints the lipid across the aperture was applied. The bilayer formation was monitored optically and electrically.

As soon as a stable bilayer has been established (C > 50 pF) the lipophilized oligonucleotide solution (8 µL, 500 nM) was injected into the cis compartment of the “Bilayer Slide”. During the incubation time of 30–40 min the bilayer integrity was monitored by continuous capacitance measurements. After the incubation of the first sample the second sample of a complementary or non-complementary oligonucleotide was injected into the cis compartment and incubated for the next 30 minutes. Subsequently, the Sybr Green I solution (8 µL, undiluted) was injected and incubated until the highest brightness amount was reached. In all graphs the brightness was given either in kHz or it was normalized (0–100%). In the meantime every 10 minutes a z-scan was performed (see below). After the incubation steps the cis compartment was perfused repeatedly for 30 s (1.1 mL/min, each), and the bilayer was inspected by a confocal fluorescence microscope. Each perfusion step using the Ionovation perfusion unit (Figure 18B) was followed by an incubation step of 10 minutes. This procedure was repeated until the brightness of the bilayer finished decreasing continuously and turned out to be stable.

A confocal laser scanning microscope (Insight Cell 3D, Evotec Technologies GmbH, Hamburg, Germany) equipped with a 488 nm argon-ion laser, (Multiline, 2014-25MLVV (max. total power 50 mW) from JDS Uniphase Corporation (Milpitas, CA,USA), as well as with a 635 nm emitting laser diode (LDH-P-635, PicoQuant, D-Berlin) und 470 nm (P-C-470B, Pico-Quart, Berlin, Germany), a 40× water-immersion objective (UApo 340, 40×, NA = 1.15, Olympus, Tokyo, Japan), and an Avalanche photodiode detector (SPCM-AQR-13-FC, Perkin-Elmer Optoelectronics, Fremont, CA, USA) were used for the optical measurements. Fluorescence irradiation was obtained with an excitation laser power of 60 ± 5 µW (for 488 nm), 200 ± 20 µW (635 nm) and 50 ± 5 µW (470 nm) right in front of the objective. Z-scans were performed by scanning the confocal laser spot in XY direction with a rotating beam scanner and movement of the objective in Z direction. The movement in all directions is piezo-controlled, which allows a nanometer precise positioning.

In summary, each measuring protocol was carried out as follows: (I) a reference scan of the stable pure bilayer was performed; (II) then the lipophilized oligonucleotide sample was added and incubated for 30 min, (III) this step was followed by the addition of the complementary and non-complementary sample, respectively, and further incubation of 30 min; (IV) finally the cyanine-dye Sybr Green I solution (DMSO) was added to allow the quantification of double stranded DNA, and the solution was incubated until the brightness in the bilayer reached the highest amount; (V) afterwards additional scan series were performed after each perfusion of the cis compart-
ment (for 30 s; 1.1 mL/min) and (VI) followed by an incubation of 10 min.

In order to analyze the 2D images they were previously edited with Image JA 1.44 and the obtained data was evaluated with OriginPro 8 (OriginLab Corporation). For an evaluation of the z-scan data, the brightness within the bilayer was measured; the mean area of the bilayer cross section amounts to 353 ± 19 counts per pixel (N = 201). Next, the brightness was determined by summing up the number of pixels. 1 Pixel equals 1 kHz or 1 µm.

All devices (Figure 18) as well as the general techniques used in this paper have been described in detail in a preceding manuscript [19].
