(Received 12 December 2011; Revised 19 June 2012)

We report new attractive force between ions that are shielded by degenerate electrons in quantum plasmas. Specifically, we show that the electric potential around an isolated ion has a hard core negative part that resembles the Lennard-Jones (LJ)-type potential. Physically, the new electric potential is attributed to the consideration of the quantum statistical pressure, the quantum Bohm potential, as well as the electron exchange and electron correlations due to electron-1/2 spin within the framework of the quantum hydrodynamical description of quantum plasmas. The shape of the attractive potential is determined by the ratio between the Bohr radius and the Wigner-Seitz radius of degenerate electrons. The existence of the hard core negative potential will be responsible for the attraction of ions forming lattices and atoms/molecules, as well as for critical points and phase transitions in quantum plasmas at nanoscales.

PACS numbers: 71.10.Ca, 63.10.+a, 67.10.Hk

A study of the potential distribution around a test charged object is of fundamental importance in many physical systems (e.g. dilute charge stabilized colloidal suspensions such as latex spheres in water, micelles and microemulsions, condensed matters with strongly correlated electrons and holes, strongly coupled dusty and quantum plasmas in laboratory and astrophysical environments, etc.), since its knowledge predicts how a cloud of opposite polarity charges will shield a test charge particle over a certain radius, which is known as the Debye-Hückel radius in the context of electrolytes and plasmas and the Thomas-Fermi/Yukawa radius in the context of condensed matters. The traditional repulsive screened Coulomb potential assumes the form \( \phi(r) = (Q/r)\exp(-r/\lambda) \), where \( Q \) is the test charge and \( \lambda \) the shielding radius of the sphere. In a classical electron-ion plasma \cite{1, 2}, an isolated ion is shielded by non-degenerate Boltzmann distributed electrons, and hence one \cite{3} replaces \( Q \) by \( Z_e \lambda \) and \( \lambda \) by the electron Debye radius \( \lambda_{De} = (kT_e/4\pi n_0 e^2)^{1/2} \), where \( T_e \) is the electron temperature, \( e \) the magnitude of the electron charge, \( k_B \) the Boltzmann constant, \( n_0 \) the electron number density. For a slowly moving test charge in collisionless \cite{4} and collisional \cite{5, 6} plasmas, there appear additional far-field potentials decreasing as inverse cube and inverse square of the distance between the test charge and the observer. In a collisionless dusty plasma \cite{7, 8} with Boltzmann distributed electrons and ions, a micron-sized negatively charged isolated dust is shielded by both positive ions and electrons. Here \( Q \) equals \( Z_d e \) and \( \lambda \) is replaced by the effective dusty plasma Debye radius \( \lambda_D = \lambda_{De} \lambda_{Di}/\sqrt{\lambda_{De}^2 + \lambda_{Di}^2} \), where \( \lambda_d \) is the number of electrons residing on a dust grain, \( \lambda_{Di} = (kT_i/4\pi n_0 e^2)^{1/2} \) the ion Debye radius, \( T_i \) the ion temperature, \( n_{i0} = n_0 + Z_d n_{d0} \) the ion number density, and \( n_{d0} \) the dust number density. In dusty plasmas with \( T_e \gg T_i \), we have \( \lambda_D \approx \lambda_{Di} \). Furthermore, in dense Thomas-Fermi plasmas with an impurity ion (with the charge state \( Z_e \)) is shielded by non-relativistic degenerate electrons, so that \( Q = Z_e \lambda \) and \( \lambda \) is replaced by the Thomas-Fermi radius \( \lambda_F = (\epsilon_F/4\pi n_0 e^2)^{1/2} \), where the electron Thomas-Fermi energy is denoted by \( \epsilon_F = (\hbar^2/2m_e k_B)(3\pi^2)^{2/3}n_0^{2/3} \), \( \hbar \) is the Planck constant divided by \( 2\pi \), and \( m_e \) the effective mass of the electrons (for example, for semiconductor quantum wells, we typically have \( m_\ast = 0.067m_e \), where \( m_e \) is the rest mass of the electrons).

In the past, tremendous progress has been made in carrying out systematic theoretical and numerical studies of phase diagrams \cite{11-17} for colloidal systems, dusty plasmas, and strongly interacting matter by supposing that like-charged particles repel each other due to the Debye-Hückel/Yukawa repulsive force. However, besides the repulsive interaction, there are also attractive forces \cite{4, 5} between two like charged particles due to the overlapping Debye spheres \cite{18} and due to the polarization of charged particulates by the sheath electric field \cite{19, 20}. Henceforth, both short range repulsive and long-range attractive potentials play a decisive role in the theory and experiments of phase transitions in colloidal and dusty plasmas.

In this Letter, we present a new attractive force between ions that are shielded by the degenerate electrons in strongly coupled quantum plasmas that are ubiquitous in a variety of physical environments (e.g. the cores of
Jupiter and white dwarf stars [21, 22], warm dense matters [23], in compressed plasmas produced by intense laser beams [24], as well as in the processing devices for modern high-technology (e.g., semiconductors [25], thin films and nano-metallic structures [26, etc.]) Specifically, we shall use here the generalized quantum hydrodynamical (G-QHD) equations [26] for non-relativistic degenerate electron fluids supplemented by Poisson’s equation. The G-QHD model includes the quantum statistical pressure and the Bohm potential [27,28] as well as the electron exchange and electron correlation effects. We demonstrate here that the electric potential around an isolated ion in quantum plasmas has a new distribution, the profile of which in special cases resembles the Lennard-Jones-type potential. It emerges that the newly found electric potential, arising from the static electron dielectric constant that includes the combined effects of statistical pressure and the quantum force [27–29], as well as the overlapping of the electron wave function due to electron-1 spin, embodies a short-range negative hard core electric potential. The latter will be responsible for Coulomb ion crystallization and oscillations of ion lattices under the new force associated with our exponential oscillating-screened Coulomb potential in strongly coupled quantum plasmas.

Let us consider a quantum plasma in the presence of non-relativistic degenerate electron fluids and mildly coupled ions that are immobile and form the neutralizing background. In our quantum plasma, the electron and ion coupling parameters are \( \Gamma_e = \frac{c^2}{a_e k_B T_F} \) and \( \Gamma_i = Z_i^2 e^2 / a_e k_B T_i \), respectively, where \( a_e \sim a_i = (3/4\pi n_0)^{1/3} \) is the average interparticle distance, and \( T_F = (\hbar^2 / 2m_e k_B)(3\pi^2 n_0)^{2/3} \) is the Fermi electron temperature. It turns out that \( \Gamma_i / \Gamma_e = Z_i^2 T_F / T_i \ll 1 \), since in quantum plasmas we usually have \( T_F > T_i \). The dynamics of degenerate electron fluids is governed by the continuity equation
\[
\frac{\partial n}{\partial t} + \nabla \cdot (n \mathbf{u}) = 0, \tag{1}
\]
the momentum equation [26]
\[
m_e \left( \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right) = e \nabla \phi - n^{-1} \nabla P + \nabla V_{xc} + \nabla V_B, \tag{2}
\]
and Poisson’s equation
\[
\nabla^2 \phi = \frac{4\pi e}{\epsilon} (n - n_0) - 4\pi Q \delta(r), \tag{3}
\]
where \( n \) is the electron number density, \( \mathbf{u} \) the electron fluid velocity, \( \phi \) the electric potential, and \( \epsilon \) the relative dielectric permeability of the material (for example, for semiconductor quantum wells we have \( \epsilon = 13 \)). We have denoted the quantum statistical pressure
\[
P = (n_0 m_e v_e^2 / 3)(n / n_0)^{5/3}, \tag{4}
\]
where \( v_e = \hbar (3\pi^2)^{1/3} / m_e r_0 \) is the electron Fermi speed and \( r_0 = n_0^{-1/3} \) represents the Wigner-Seitz radius, and the sum of the electron exchange and electron correlations potential is [33]
\[
V_{xc} = 0.985(e^2 / \epsilon) n^{1/3} \left[ 1 + (0.034 / a_B n^{1/3}) \ln(1 + 18.37 a_B n^{1/3}) \right], \tag{5}
\]
where \( a_B = \hbar^2 / m_e e^2 \) represents the effective Bohr radius. The quantum Bohm potential is [30, 32]
\[
V_B = (\hbar^2 / 2m_e)(1 / \sqrt{n}) \nabla^2 / \sqrt{n}. \tag{6}
\]
We have thus retained the desired quantum forces that act on degenerate electrons in our non-relativistic quantum plasma. The quantum hydrodynamic equations (1)-(3) are valid [26, 34, 35] if the plasmonic energy density \( \hbar \omega_{pe} \) is smaller (or comparable) than (with) the Fermi electron kinetic energy \( k_B T_F \), where \( \omega_{pe} = (4\pi n_0 e^2 / m_e)^{1/2} \) is the electron plasma frequency, and the electron-ion collision relaxation time is greater than the electron plasma period.

Letting \( n = n_0 + n_1 \), where \( n_1 \ll n_0 \), we linearize the resultant equations to obtain the electron density perturbations which can be inserted into Eq. (3). The Fourier transformation in space leads to the electric potential around an isolated ion. In the linear approximation, we have [4, 36]
\[
\phi(r) = \frac{Q}{2\pi^2} \int \frac{\exp(i\mathbf{k} \cdot \mathbf{r})}{k^2 D} d^3k, \tag{7}
\]
where \( \mathbf{r} \) denotes the position relative to the instantaneous point of the test charge, and the dielectric constant for a dense quantum plasma with quasi-stationary density perturbations is given by
\[
D = 1 + \frac{\omega_{pe}^2}{k^2 (v_e^2 / 3 + v_{ex}^2) + \hbar^2 k^4 / 4m_e^2}. \tag{8}
\]
Here we have denoted \( v_{ex} = (0.328 e^2 / m_e r_0)^{1/2} (1 + 0.62 / (1 + 18.36 a_B n_0^{1/3}))^{1/2} \).

The inverse dielectric constant can be written as
\[
\frac{1}{D} = \frac{(k^2 / k_s^2) + \alpha k^4 / k_s^4}{1 + (k^2 / k_s^2) + \alpha k^4 / k_s^4}, \tag{9}
\]
where \( k_s = \omega_{pe} / \sqrt{v_e^2 / 3 + v_{ex}^2} \) is the inverse Thomas-Fermi screening length, and \( \alpha = \hbar^2 \omega_{pe} / 4m_e^2 (v_e^2 / 3 + v_{ex}^2)^{3/2} \) measures the importance of the quantum recoil effect. If \( m_s = m_e, \epsilon = 1 \) then \( \alpha \) depends only on \( r_0 / a_B \) with \( a_B = \hbar^2 / m_e e^2 \). Inserting Eq. (6) into Eq. (7), the latter can be written as
\[
\phi(r) = \frac{Q}{4\pi^2} \int \left[ \frac{(1 + b)}{k^2 + k_s^2} + \frac{(1 - b)}{k^2 + k_s^2} \right] \exp(i\mathbf{k} \cdot \mathbf{r}) d^3k, \tag{10}
\]
where \( b = 1 / \sqrt{1 - 4\alpha}, \) and \( k_s^2 = k_0^2 [1 + \sqrt{1 - 4\alpha}] / 2\alpha. \)

Here, we use \( \sqrt{1 - 4\alpha} = i\sqrt{4\alpha - 1} \) for \( \alpha > 1/4 \). The integral in Eq. (10) can be evaluated using the general formula
\[
\int \frac{\exp(i\mathbf{k} \cdot \mathbf{r})}{k^2 + k_s^2} d^3k = 2\pi^2 \frac{\exp(-k_s r)}{r}, \tag{11}
\]
where the branches of $k_\pm$ must be chosen with positive real parts so that the boundary condition $\phi \to 0$ at $r \to \infty$ is fulfilled.

First, for $\alpha > 1/4$, the solution of the equation $k_+^2 = k_0^2(1+i\sqrt{4\alpha-1})/2\alpha$ yields $k_+ = (k_0/\sqrt{4\alpha})[(\sqrt{4\alpha} + 1)^{1/2} + i(\sqrt{4\alpha - 1})^{1/2}] = k_0 + ik_i$, and the electric potential

$$\phi(r) = \frac{Q}{r} \left[ \cos(k_0 r) + b_s \sin(k_0 r) \right] \exp(-k_0 r),$$  

where $b_s = 1/\sqrt{4\alpha - 1}$. In the limit $h^2 k_0^2 \gg 4m_0^2 (v_s^2/3 + v_{es}^2)$, we recover the exponential cosine-screened Coulomb potential \[37\]

$$\phi(r) = \frac{Q}{r} \cos(k_0 r) \exp(-k_0 r),$$

where $r = r/(4\alpha)^{1/4}$. Second, for $\alpha \to 1/4$, we have $k_+ = k_- = \sqrt{2}k_0$, and

$$\phi(r) = \frac{Q}{r} \left(1 + \frac{k_0 r}{\sqrt{2}}\right) \exp(-\sqrt{2}k_0 r).$$

Third, for $\alpha < 1/4$, the expression $\sqrt{1 - 4\alpha}$ is real, and we obtain $k_+ = k_0(1 + \sqrt{1 - 4\alpha})^{1/2}/\sqrt{2\alpha}$. The resultant electric potential is

$$\phi(r) = \frac{Q}{2r} \left[(1+b) \exp(-k_+ r) + (1-b) \exp(-k_- r)\right].$$

We note that in the limit $\alpha \to 0$, we recover from \[12\] the modified Thomas-Fermi screened Coulomb potential $\phi(r) = (Q/r) \exp(-k_0 r)$. Furthermore, the newly found electrical potential, given by Eq. \[12\], is significantly different from that potential [e.g. Eq. (13) in Ref. \[36\]], indicating that the electric potential is proportional to $r^{-3} \cos(2k_F r)$, where $k_F = p_F/h = |k||2$ is the Fermi wave number and $p_F$ the Fermi electron momentum which involves the Friedel oscillations \[38\] arising from the Kohn anomaly \[39\] related with the discontinuous Fermi surface.

![FIG. 2: The electric potential $\phi$ as a function of $r$ for $\alpha = 0.625$ (dashed curve), $\alpha = 1/4$ (solid curve) and $\alpha = 0$ (dotted curve). The value 0.627 is the maximum possible value of $\alpha$ in our model, obtained for $a_B/r_0 \approx 0.15.$](image)

![FIG. 3: a) The distance $r = d$ from the test ion charge where $d\phi/dr = 0$ and the electric potential has its minimum, and b) the values of the potential $\phi$ and c) its second derivative $d^2\phi/dr^2$ at $r = d.$](image)
(\frac{d^2 \phi}{dr^2}) determines the oscillation frequency and dispersive properties of the plasma as shown below. For \( \alpha \leq 0.25 \), the electric potential and its second derivative vanish, and there is no attractive potential associated with the stationary test ion charge. Furthermore, we note that the shielding of a moving test charge and bound states near a moving charge in a quantum plasma have been investigated by Else et al. \[40\] by using the Lindhard dielectric function \[41\] that ignores the electron exchange and electron correlation effects.

The interaction potential energy between two dressed ions with charges \( Q_i \) and \( Q_j \) at the position \( \mathbf{r}_i \) and \( \mathbf{r}_j \) can be represented as \( U_{ij}(\mathbf{R}_{ij}) = Q_i \phi_i(\mathbf{R}_{ij}) \), where \( \phi_i \) is the potential around particle \( i \), and \( \mathbf{R}_{ij} = \mathbf{r}_i - \mathbf{r}_j \). For \( \alpha > 1/4 \), it reads, using Eq. 9,

\[
U_{ij}(\mathbf{R}_{ij}) = \frac{Q_i Q_j}{|\mathbf{R}_{ij}|} \exp(-k_r|\mathbf{R}_{ij}|)
\times \left[ \cos(k_z|\mathbf{R}_{ij}|) + b_s \sin(k_z|\mathbf{R}_{ij}|) \right].
\] (13)

On account of the interaction potential energy, ions would suffer vertical oscillations around their equilibrium position. The vertical vibrations of ions in a crystallized ion string in quantum plasmas are governed by

\[
M \frac{d^2 \delta z_j(t)}{dt^2} = -\sum_{i\neq j} \frac{\partial U_{ij}(\mathbf{r}_i, \mathbf{r}_j)}{\partial \delta z_j},
\] (14)

where \( \delta z_j(t) = z_j(t) - z_{j0} \) is the vertical displacement of the \( j \)th ion from its equilibrium position \( z_{j0} \), and \( M \) the mass of the ion. Assuming that \( \delta z_j(t) \) is proportional to \( \exp[-i(\omega t - jka)] \), where \( \omega \) and \( k \) are the frequency and wave number of the ion lattice oscillations, respectively, and that \( Q_i = Q_j = Q \), Eq. (13) for the nearest-neighbor ion interactions gives

\[
\omega^2 = \frac{4Q^2}{M} S \exp(-k_r d) \sin^2 \left( \frac{kd}{2} \right),
\] (15)

where \( S = [2(1 + k_r d) + (k_r^2 - k_d^2)d^2](\cos \xi + b_s \sin \xi) + 2k_d d(1 + k_r d)(\sin \xi - b_s \cos \xi) \). \( \xi = k_d d \), and \( d \) is the separation between two consecutive ions. We note that Eq. (15) can also be obtained from the formula \[42\]

\[
\omega^2 = \frac{4}{M} \left[ \frac{d^2 W(r)}{dr^2} \right]_{r=d} \sin^2 \left( \frac{kd}{2} \right).
\] (16)

where the inter-ion potential energy is represented as \( W(r) = (Q^2/r) \exp(-k_r r) [\cos(k_r r) + b_s \sin(k_r r)] \) for \( \alpha > 1/4 \). Hence, the lattice wave frequency is proportional to \( [d^2 \phi(r)/dr^2]_{r=d}^{1/2} \) [cf. Fig. 3(c)], and vanishes for \( \alpha < 0.25 \).

Summing up, we have discovered a new attractive force between two ions that are shielded by degenerate electrons in an unmagnetized quantum plasma. There are several consequences of our newly found short-range attractive force at quantum scales. For example, due to the trapping of ions in the negative part of the exponential oscillating-screened Coulomb potential, there will arise ordered ion structures depending the electron density concentration, which in fact controls the Wigner-Seitz radius \( r_0 \). The formation of ion clusters/ion atoms will emerge as new features that are attributed to the new electric potential we have found here. Finally, under the action of the attractive force, we can have the formation of Coulombic ion lattices (Coulomb ion crystallization) and ion lattice vibrations, as well as the phenomena of phase separations at nanoscales in dense quantum plasmas (e.g. from solid to liquid-vapor phases) depending upon how one controls the ratio \( r_0/a_B \). Thus, the ratio between the interaction energy between the two nearest-neighbor ions in the presence of the oscillating exponential Coulomb potential and the ion thermal energies, as well as the inter-particle spacing are the key parameters which will determine a critical point that is required for phase transitions in quantum plasmas. In conclusion, the present investigation, which has revealed the new physics of collective electron interactions at nanoscales, will open a new window for research in one of the modern areas of physics dealing with strongly coupled degenerate electrons and non-degenerate mildly coupled ions in dense plasmas that share knowledge with cooperative phenomena (e.g. the formation of ion lattices) in condensed matter physics and in astrophysics. Thus, the present investigation contributes to enhancing the existing knowledge of Wigner crystallization in two-component Coulomb systems \[43\] \[44\] that do not account for an attractive force between like charged particles.
