ABSTRACT

This paper presents a study of the galactic environment of a chemically-pristine ($< 0.6\%$ solar metallicity) Lyman Limit system (LLS) discovered along the sightline toward QSO SDSSJ 135726.27+043541.4 ($z_{\text{QSO}} = 1.233$) at projected distance $d = 126$ physical kpc (pkpc) from a luminous red galaxy (LRG) at $z = 0.33$. Combining deep Hubble Space Telescope images, MUSE integral field spectroscopic data, and wide-field redshift survey data has enabled an unprecedented, ultra-deep view of the environment around this LRG-LLS pair. A total of 12 galaxies, including the LRG, are found at $d < \sim 400$ pkpc and line-of-sight velocity $\Delta v < 600$ km s$^{-1}$ of the LLS, with intrinsic luminosity ranging from $0.331 L_\star$ to $2 L_\star$ and a corresponding stellar mass range of $M_{\text{star}} \approx 10^7 - 10^{11} M_\odot$. All 12 galaxies contribute to a total mass of $M_{\text{star}} = 1.6 \times 10^{11} M_\odot$ with $\sim 80\%$ contained in the LRG. The line-of-sight velocity dispersion of these galaxies is found to be $\sigma_{\text{group}} = 230$ km s$^{-1}$ with the center of mass at $d_{\text{group}} = 118$ pkpc and line-of-sight velocity offset of $\Delta v_{\text{group}} = 181$ km s$^{-1}$ from the LLS. Three of these are located at $d \lesssim 100$ pkpc from the LLS, and they are all faint with intrinsic luminosity $< 0.02 L_\star$ and gas phase metallicity of $\approx 10\%$ solar in their interstellar medium. The disparity in the chemical enrichment level between the LLS and the group members suggests that the LLS originates in infalling intergalactic medium and that parts of the intergalactic gas near old and massive galaxies can still remain chemically pristine through the not too distant past.

Key words: haloes – galaxies: elliptical and lenticular, cD – quasars: absorption lines – intergalactic medium – galaxies: formation

1 INTRODUCTION

Luminous red galaxies (LRGs) are selected based on their photometric and spectroscopic properties that resemble nearby elliptical galaxies (e.g., Eisenstein et al. 2001). These galaxies comprise primarily old stars with little/no on-going star formation (e.g., Roseboom et al. 2006; Gauthier & Chen 2011) and represent more than 90% of massive galaxies with stellar mass $M_{\text{star}} \gtrsim 10^{11} M_\odot$ (e.g., Peng et al. 2010; Tinker et al. 2013) with a corresponding dark matter halo mass of $M_h > 10^{13} M_\odot$ (Blake et al. 2008). There-
fore, they offer an ideal laboratory for studying feeding and feedback in massive halos that are generally free of complex starburst driven winds (see Chen 2017 for a recent review).

Motivated by previous studies that reported abundantly enriched cool gas in LRG halos (e.g., Gauthier et al. 2009, 2010, Lundgren et al. 2009; Gauthier & Chen 2011; Bowen & Chelouche 2011; Zhu et al. 2014; Huang et al. 2016), we are carrying out a UV absorption-line survey to study the circumgalactic medium (CGM) around 16 LRGs using the Cosmic Origins Spectrograph (COS) on board the Hubble Space Telescope (HST) (Chen et al. 2018; hereafter Paper I). The LRGs in this COS-LRG sample were selected uniformly with stellar mass $M_{\text{star}} > 10^{11} \, M_\odot$ and no prior knowledge of the presence/absence of any absorption features. The program was designed to enable accurate measurements of the neutral hydrogen column density $N(\text{H}^i)$ based on observations of the full Lyman series. This COS-LRG sample therefore allows a systematic study of the ionization state and chemical enrichment of the CGM in massive quiescent halos.

The main findings from our initial analysis presented in Paper I can be summarized as follows. First, high-$N(\text{H}^i)$ gas is common in these massive quiescent halos with a median of $\langle \log N(\text{H}^i)/\text{cm}^{-2} \rangle = 16.6$ at projected distances $d \lesssim 160 \, \text{physical kpc (pkpc)}$. For all but three LRGs the associated Lyman absorption series is detected. The mean covering fraction of optically-thick absorbers with $\log N(\text{H}^i)/\text{cm}^{-2} \gtrsim 17.2$ is found to be $\langle \kappa \rangle_{17.2} = 0.44^{+0.12}_{-0.11}$ at $d \lesssim 160 \, \text{pkpc}$ and $\langle \kappa \rangle_{17.2} = 0.71^{+0.11}_{-0.20}$ at $d \lesssim 100 \, \text{pkpc}$. Secondly, the gas has been enriched with heavy elements with $\text{C} \, \text{m} / 977$ and $\text{Si} \, \text{m} / 1206$ absorption lines being the most dominant features. The observed high covering fraction of C or absorbing gas in LRG halos is statistically consistent with what is seen in COS-Halos blue galaxies. The “bimodality” observed in O vi absorbing gas between star-forming and quiescent galaxies (e.g., Chen & Mulchaey 2009; Tumlinson et al. 2011) is not seen in these intermediate ions. Finally, while the line-of-sight velocity separations between the H i absorbing gas and LRGs are characterized by a mean and dispersion of $\langle v_{\text{gas-LRG}} \rangle = 29 \, \text{km} \, \text{s}^{-1}$ and $\sigma_{\text{gas-LRG}} = 171 \, \text{km} \, \text{s}^{-1}$, eight of the 13 LRG halos with detected absorption features were resolved into multiple components with velocities separated by at much as $\approx 360 \, \text{km} \, \text{s}^{-1}$.

In a follow-up study, Zahedy et al. (2018; hereafter Paper II) performed a detailed component by component analysis that simultaneously incorporated multiple ionic transitions for constraining the density, $n_\text{H}$, and metallicity, $[M/\text{H}]$, of the CGM in LRG halos based on comparisons with a grid of Cloudy (Ferland et al. 2013; v13.03) ionization models. An interesting finding of Paper II is that the derived gas metallicities of individual components can vary by more than an order of magnitude in a single LRG halo, from $< 1/10$ solar to super solar irrespective of the adopted ionizing spectrum. This applies to gas both at $d < 100 \, \text{pkpc}$ and beyond. In addition, solar-metallicity gas is observed out to $d = 160 \, \text{pkpc}$ in half of the COS-LRG sample, while metal-poor gas of metallicity $\lesssim 1/100$ solar is also found in at least three cases. Similarly, the inferred gas densities vary by two orders of magnitude between individual components in a single halo, from $n_\text{H} \approx 0.1 \, \text{cm}^{-3}$ to $n_\text{H} \lesssim 0.001 \, \text{cm}^{-3}$, while the mean gas density averaged over all components is $\langle n_\text{H} \rangle \approx 0.005 - 0.01 \, \text{cm}^{-3}$ for the majority of LRG halos at $d = 40 - 160 \, \text{pkpc}$.

In one particular LRG halo, SDSSJ 135727.27+043603.3 at $z = 0.3295$, we detected a strong absorber of $\log N(\text{H}^i)/\text{cm}^{-2} = 17.48 \pm 0.01$, a Lyman limit system (LLS), at $d = 126 \, \text{pkpc}$ and $\Delta z_{\text{LLS}} = 0.3287$ which yields a line-of-sight velocity offset of $v_{\text{gas-LRG}} \approx -180 \, \text{km} \, \text{s}^{-1}$. This LLS is characterized by a single component of Doppler parameter $b_{\text{HI}} = 18 \, \text{km} \, \text{s}^{-1}$ and no associated metal ion features down to sensitive column density limits (Figure 1). The observed simple absorption profiles of the hydrogen lines place a strong constraint on the gas temperature at $T < 2 \times 10^4 \, \text{K}$. A 95% upper limit to the gas metallicity of $[M/\text{H}] < -2.2$ was obtained for the LLS based on the non-detections of any metal transitions and a size limit of $\lesssim 1 \, \text{kpc}$ for the absorber (Paper II). The low metallicity limit is also confirmed by Lehner et al. (2018), who report $[\text{Mg}/\text{H}] = -2.3 \pm 0.2$ for this absorber. Not only is the observed metal content significantly lower than the typical solar metallicity found in nearby elliptical galaxies (e.g., Mathews & Bright GMT 2003) or the near-solar metallicity of the interstellar medium (ISM) of an intermediate-redshift elliptical (Zahedy et al. 2017), it is also among the most metal-poor LLSs found at $z < 1$ (e.g., Ribaudo et al. 2011; Lehner et al. 2018). The observed chemically-pristine gas near a massive quiescent galaxy strongly suggests that the LLS originates in infalling gas clouds from the intergalactic medium (IGM).

Here we present deep wide-field integral field spectroscopic data from the MUSE-QuBuzz program (PI: Schaye; see also Segers et al. 2018 & Straka et al. 2018, in preparation), wide-field multi-object spectroscopic data obtained using the Low Dispersion Survey Spectrograph 3 (LDDS3) on the Magellan Clay Telescope, and exquisite Hubble Space Telescope (HST) imaging data (PI: Straka) of the field. These imaging and spectroscopic data together provide a high-definition view of the galaxy environment around the chemically-pristine LLS and the LRG at $z = 0.33$, and offer valuable insights into the origin of chemically-pristine gas observed near a massive, quiescent galaxy. The paper is organized as follows. In Section 2, we describe the imaging and spectroscopic observations, and the construction of photometric and spectroscopic catalogs of faint galaxies in the field. In Section 3, we present properties of all galaxies identified in the vicinity of the chemically-pristine LLS at $z = 0.33$. In Section 4, we discuss the implications of our findings. Throughout the paper, we adopt $12 + \log(\text{O}/\text{H}) = 8.69 \pm 0.05$ for the solar oxygen abundance (Asplund et al. 2009), and a standard Λ cosmology, $\Omega_m = 0.3$ and $\Omega_{\Lambda}=0.7$ with a Hubble constant $H_0 = 70 \, \text{km} \, \text{s}^{-1} \, \text{Mpc}^{-1}$.

### 2 OBSERVATIONS AND DATA ANALYSIS

To carry out a deep galaxy survey around the LRG and the associated chemically-pristine LLS at $z = 0.33$, we have assembled deep imaging and spectroscopic data both from

---

1 The error quoted above represents only statistical uncertainties. Systematic uncertainties due to continuum placement errors are not included. For comparison, Lehner et al. (2018) reports $\log N(\text{H}^i)/\text{cm}^{-2} = 17.55 \pm 0.05$ for this system.
Figure 1. A subset of absorption transitions of the LLS with log \(N(H_\text{I})/cm^{-2} = 17.48 \pm 0.01\) at \(d = 126\) pkpc from LRG SDSSJ 135727.27+043603.3 at \(z_{\text{LLS}} = 0.3287\) (see Chen et al. 2018 and Zahedy et al. 2018 for a complete list). Contaminating SDSSJ 135727.27+043603.3 at \(z = 0\). The vertical dotted line marks the relative line-of-sight velocity of the LRG at +180 km s\(^{-1}\). The hydrogen Lyman series lines displayed in the left panels are characterized by a single component of \(b_{\text{HI}} = 18\) km s\(^{-1}\), constraining the gas temperature to be \(T < 2 \times 10^4\) K. In contrast, no heavy ions are detected to sensitive upper limits (right panels). The 95\% upper limits to the underlying ionic column densities in logarithmic values are shown in the lower-right corner of the right panels.

2.1 Imaging observations and the object catalog

our own observations and from the public archives. Here we describe the observations and data analysis.

2.2 MUSE integral field spectroscopic observations

Wide-field integral field spectroscopic data of the QSO field have been obtained using the Multi-Unit Spectroscopic Explorer (MUSE; Bacon et al. 2010), as part of the MUSE Quasar-field Blind Emitter Survey (MUSE-QuBES; PI: Schaye. MUSE observes a field of \(1' \times 1'\) at a pixel scale of 0.2\'' and a spectral resolution of FWHM \(\approx 120\) km s\(^{-1}\) at 7000 Å. It enables a deep search of faint galaxies within 140 pkpc in projected distance of the QSO sightline at \(z = 0.33\). The observations were carried out in May of 2015, in blocks of one hour each for a total of two hours. Each observing block was split into four exposures of 900 s each. Small dithers of a few arcseconds in the telescope pointing and offsets in the position angle in steps of 90 degrees were applied between exposures to smooth out the tiling pattern in the combined data cube. Individual exposures were first applied between exposures to smooth out the tiling pattern and reach a 5-\(\sigma\) depth of 23.6 mag for extended sources. Coadded \(g\)-, \(r\)-, and \(z\)-band images of the field and the associated object catalog were retrieved from the DECaLS data release 5 website. The mean seeing conditions in the coadded images are characterized by a full-width-at-half-maximum (FWHM) for point sources of 1\''\'', 0.9\''\'', and 0.8\''\'' in the \(g\)-, \(r\)-, and \(z\)-band, respectively. The available \(g\)-, \(r\)-, and \(z\)-band photometric measurements provide constraints for the broad-band spectral energy distributions of relatively bright objects. The stacked \(r\)-band image is presented in Figure 2.

We have also obtained high-quality Hubble Space Telescope (HST) images of the field using the Wide Field Channel (WFC) in the Advanced Camera for Surveys (ACS) and the F814W filter (PID=14660; PI: Straka). The observations were carried out on 2017 July 5 UT. Four exposures of 543 s each were obtained and processed using the standard HST\'s reduction pipeline. Individual frames were corrected for geometric distortion using drizzle, registered to a common origin, filtered for deviant pixels, and combined to form a final stacked image. The final stacked F814W image covers a region of roughly 3\'' \times 3.5\'' and reaches a 5-\(\sigma\) limiting magnitude of \(AB(F814W) = 27.2\) over a 0.5-diameter aperture, significantly deeper than the public \(g\)-, \(r\)-, and \(z\)-band images from DECaLS. The F814W image replaces the DECaLS \(r\)-band image in Figure 2 in the overlapping region. In addition to resolving galaxy morphologies, the HST ACS/F814W image uncovers more than twice as many faint galaxies as found in the DECaLS images.

While the greater depth and higher spatial resolution of the HST/ACS F814W image make the F814W an ideal choice for detections of faint galaxies, the available DECaLS data provide a wider field coverage for studying the large-scale environment. To construct the object catalog, we first adopted the public photometric catalog from DECaLS. For the area that is also covered by the HST/ACS F814W image, we performed source detections in the F814W image using the SExtractor program (Bertin & Arnouts 1996) and identified additional faint objects with \(AB(F814W) < 27\) mag. We then combined the DECaLS and F814W catalogs to form a master catalog by matching object coordinates. Nearly all objects with \(AB(F814W) < 23.5\) mag have an entry in the DECaLS catalog. For objects that are not detected in the DECaLS images, the 5-\(\sigma\) limiting magnitudes computed for extended sources in this region by the DECaLS team are adopted (see e.g., Dey et al. 2018).
Figure 2. The field centered at QSO SDSSJ 135726.27+043541.4 at $z_{\text{QSO}} = 1.233$ observed in DECaLS r-band (grey-scale image) and in HST/ACS and the F814W filter (displayed in heat map). The dashed circles mark the 1’ and 2’ radii from the QSO sightline. The dotted square box marks the field of view of MUSE observations (see § 2.2 and Figure 3 below). Spectroscopically identified objects from the LDSS3 survey are marked with redshift measurements next to them (see § 2.3). Galaxies associated with the pristine LLS at $z = 0.33$ from the combined LDSS3 and MUSE survey are labeled G1 through G12 in red. The DECaLS image reaches a 5-σ limiting magnitudes of $AB(r) = 24.4$ for extended sources. The HST/ACS image (PID=14660; PI: Straka) reaches a 5-σ limiting magnitude of $AB(F814W) = 27.2$ over a 0.5″-diameter aperture, providing resolved morphologies for DECaLS identified objects and revealing fainter objects missed in the DECaLS imaging data. The previously identified LRG is G5 at $\approx 27''$ ($d = 126$ pkpc) northeast of the QSO at $z = 0.3295$, surrounded by two other compact and fainter neighbors at similar redshifts (see Tables 1 & 2 below, and Figure 3 for a zoom-in view). Combining deep imaging and spectroscopic data has uncovered an overdensity of faint galaxies at $d < 400$ pkpc from the pristine LLS at $z = 0.33$. 
reduced using the standard MUSE data reduction pipeline (v1.2; Weibacher et al. 2012) and further processed using the CubExtractor package (Cantalupo et al., in prep; see also Borissova et al. 2016; Marino et al. 2018), which include bias subtraction, flat-fielding, illumination correction, and wavelength and flux calibrations. (see Seegers et al. 2018 for a detailed description).

Within the MUSE 1′ × 1′ field of view, we identified 110 objects of $AB(F814W) < 27$ mag, of which 47 are identified in the DECaLS photometric catalog. All but one of the remaining 63 objects are faint with $AB(F814W) > 23.5$ mag and do not have an entry in the DECaLS catalog. The only exception is J135727.50+043601.98 (G6 in Figures 2 & 3) with $AB(F814W) = 22.35$ mag, which occurs at $≈ 3′$ from the LRG (G5) with $AB(r) = 19$ mag and $AB(F814W) = 18.66$ mag. The close proximity to a bright galaxy may have made object deblending challenging in ground-based images. As discussed below, the MUSE spectrum of this galaxy exhibits absorption features that are consistent with a passive galaxy at $z = 0.3303$, similar to the LRG but nearly four magnitudes fainter. We therefore estimated the $g$, $r$, and $z$-band magnitudes of this faint satellite based on the observed brightness of the LRG in these bandpasses.

For every object detected in the F814W image, we extracted a mean spectrum and the associated error spectrum over a circular aperture centered at the object position in the MUSE data cube. The aperture size was adjusted according to the object brightness. Within the MUSE field, two objects (the QSO and LRG) have optical spectra available from the SDSS spectroscopic archive. Comparisons of SDSS spectra and our own MUSE spectra of these objects show good agreement both in the locations of the line features and in the relative fluxes across the full spectral range from $\lambda \approx 4900$ Å to $\lambda > 9200$ Å, confirming the accuracy of wavelength and flux calibrations in the MUSE data cube.

2.3 LDSS3 multi-object spectroscopic observations

Multi-object spectroscopic observations of the QSO field were obtained using the Low Dispersion Survey Spectrograph 3 (LDSS3) and the VPH-all grism on the Magellan Clay telescope. LDSS3 observes a field of 4′ in radius at a pixel scale of 0.189′′, expanding the redshift survey beyond the MUSE field of view and providing a wider view of the large-scale galactic environment around the LRG and the pristine LLS at $z = 0.33$. The VPH-all grism covers a wavelength range of 4500 – 10000 Å with a spectral resolution of FWHM $\approx 400$ km s$^{-1}$. Multiple slitmasks were designed to observe a total of 247 objects with $AB(r) < 23.5$ mag which, at $z = 0.33$, corresponds to $> 0.05 L^*$ in intrinsic luminosity. Objects at $< 30′′$ in angular distance from the QSO sightline were excluded from the LDSS3 observations to minimize duplicated spectroscopic follow-up effort, given the existing MUSE data. The observations were carried out in March 2018 and each mask was exposed for a total of 80 minutes under sub-arcsecond seeing conditions. The data were reduced using the COSMOS pipeline described in Chen & Mulchaey (2009).

2.4 The redshift survey

To determine the redshift of each object, we performed a $\chi^2$ fitting routine that compares the observed spectrum with models formed from a linear combination of four eigen-spectra from the SDSS at different redshifts (see Chen & Mulchaey 2009 and Johnson et al. 2013 for a detailed description). The best-fit redshift of each object returned from the $\chi^2$ routine was visually inspected for confirmation.

From the MUSE data, we were able to obtain robust redshift measurements for 67 F814W-identified objects. Redshift uncertainties based on MUSE spectra are typically $\Delta z \lesssim 0.0001$ for emission-line galaxies and $\Delta z \approx \pm 0.0003$ for absorption-line galaxies. All but one of the 42 objects brighter than $AB(F814W) = 24$ mag in the 1′ × 1′ MUSE field are identified with a spectroscopic redshift, reaching nearly 100% survey completeness for objects with $AB(F814W) < 24$ mag. In addition, 26 galaxies fainter than $AB(F814W) = 24$ mag have redshift identifications based on observations of strong emission lines, maintaining a 50% completeness level for objects with $AB(F814W) = 25$ – 26 mag. The faintest spectroscopically identified galaxy is J135726.81+043544.27 of $AB(F814W) \approx 27$ mag at $z = 0.3313$, close in redshift and projected distance to the LRG and the LLS.

From the LDSS3 observations, we were able to obtain robust redshift measurements for 146 objects of $AB(r) < 23.4$ mag at angular separations of 0.5′ – 3.3′ from the QSO sightline, including six objects that were also covered by the MUSE observations. Redshift uncertainties based on LDSS3 spectra are typically $\Delta z \approx \pm 0.0003$. Over the annulus of 0.5′ – 2′ radius of the QSO sightline, corresponding to 150 – 570 pkpc at $z = 0.33$, the LDSS3 survey reached > 80% completeness for extended sources of $AB(r) \leq 22$ mag, > 70% for objects of $AB(r) < 23$ mag, and > 60% for objects of $AB(r) < 23.5$ mag.

The results of the LDSS3 survey are summarized in Figure 2 with each spectroscopically identified object marked by the best-fit redshift. The redshift measurements are shown to two decimal places to avoid crowding. Galaxies found near the LLS from the combined LDSS3 and MUSE survey are labeled G1 through G12 in red. Redshift measurements of these galaxies are presented in column (4) of Table 1. Figure 2 shows that the LDSS3 and MUSE survey data together have uncovered an overdensity of galaxies near the LLS within 500 pkpc in radius.

The results of the MUSE survey in the inner 1′ × 1′ field around the QSO are summarized in Figure 3, which demonstrates that the high-throughput and dense sampling of MUSE enable a high survey completeness to faint magnitudes (see § 3 below). The left panel shows the HST/ACS F814W image, while the right panel displays a narrow-band image of 20 Å wide, centered at 6660 Å from the combined MUSE data cube. The wavelength range is chosen to match the expected wavelength of [OIII] 5007Å at the redshift of this galaxy group, $z = 0.33$. The circles highlight the three line-emitting objects that are barely detected in the F814W band.
Figure 3. Zoom-in view of the field centered on QSO SDSSJ 135726.27+043541.4 at $z_{\text{QSO}} = 1.233$, with the HST/ACS F814W image displayed on the left and a narrow-band image of 20 Å wide, centered at 6660 Å from the combined MUSE data cube displayed on the right. North is up and east to the left. At $z = 0.33$, the wavelength range of the narrow-band image corresponds to the observed wavelength of [O III] $\lambda$5007. The dashed circle marks the 30′′ radius from the QSO sightline, corresponding to $d \approx 140$ pkpc at $z = 0.33$. Similar to Figure 2, spectroscopically identified objects are marked with their redshift measurements and galaxies associated with the pristine LLS at $z = 0.33$ are highlighted in red. In the MUSE narrow-band image, precise redshifts of the galaxies in the vicinity of the LLS (G1 through G7) are presented. The F814W image and MUSE data together provide a detailed view of additional neighbors closer in projected distance to the LLS than the LRG (G5), three of which are emission-line dominated galaxies with exceedingly faint continuum fluxes (G1, G2, and G3; also marked in circles).
Table 1. Photometric properties of galaxies in the vicinity of the LLS at $z = 0.3287$

| ID        | Coordinates (arcsec) | $\vartheta$ | $z$ | $d$ (pkpc) | $AB(g)$ | $AB(r)$ | $AB(z)$ | $AB(F814W)$ |

The LRG identified in the SDSS spectroscopic sample. The redshift determined from MUSE data agrees with the SDSS measurement.

This object is not identified in the DECaLS catalog, possibly due to blending with the LRG at $\approx 3''$ away.

We estimate the $g,r,z$ magnitudes based on its observed flux ratio relative to the LRG in the F814W band.

3 GALACTIC ENVIRONMENT OF THE LLS AT $Z = 0.33$

The analysis presented in § 2 yielded a highly complete spectroscopic sample of galaxies in the field around QSO SDSS J135726.27+043541.4. Specifically at angular distances $\theta > 30''$ from the sightline, the MUSE survey reached nearly 100% completeness for objects with $AB(F814W) < 24$ mag and 50% completeness for objects with $AB(F814W) = 24 - 25$ mag. At $z = 0.33$, the observed F814W bandpass corresponds well with rest-frame r-band, and from Cool et al. (2012) blue galaxies at this redshift are found to have a characteristic rest-frame absolute magnitude of $M_r = -21.3$ and red galaxies have $M_r = -21.5$. An observed brightness of $AB(F814W) = 24$ (25) mag therefore corresponds to $\approx 0.02$ ($0.007$) $L_r$ at $z = 0.33$.

Over the angular distance range from $\theta > 30''$ to $\theta > 2'$, the LDBSS survey reached $> 80\%$ completeness for objects with $AB(r) < 22$ mag and $> 70\%$ completeness for objects with $AB(r) < 23$ mag. At $z = 0.33$, the survey limit at $AB(r) = 23$ mag corresponds to 0.08$L_r$ for quiescent galaxies and 0.05$L_r$ for star-forming galaxies. The highly complete imaging and spectroscopic data therefore provide an ultra deep view of the galactic environment of the chemically-pristine LLS and the nearby LRG.

Indeed, our imaging and spectroscopic survey of this field has uncovered a group of 12 galaxies in the vicinity of the LLS at $z = 0.33$. The photometric properties of these galaxies are presented in columns (6) through (9) of Table 1, in increasing angular distance from the QSO ($\theta$ in column 3). For objects that are not detected in the DECaLS images, the 5-σ limiting magnitudes computed for extended sources in this region by the DECaLS team (e.g., Dey et al. 2018) are provided in Table 1.

In addition to the previously identified LRG at $d = 126$ pkpc, our survey yielded 11 new galaxies with rest-frame absolute r-band magnitude ranging from $M_r = -14$ to $M_r = -19.6$ (corresponding to a luminosity range of 0.001$L_r$ to 0.2$L_r$) at $d = 39 - 386$ pkpc, and no additional member at $d > 400$ pkpc. In comparison to the LRG, a 2$L_r$ evolved galaxy (estimated based on the observed F814W brightness and $\approx 30\%$ less luminous than the previous estimate from SDSS) with an implied virial radius of $\approx 500$ pkpc (e.g., Gauthier et al. 2009; Huang et al. 2016), the newly identified galaxies are all significantly fainter and the three galaxies closest to the QSO sightline are line emitters with exceedingly faint optical continuum magnitudes, $AB(r) > 24.4$ mag (galaxies G1, G2, & G3 circled in Figure 3).

We infer a stellar mass, $M_{\text{star}}$, for each member of the galaxy 'group' based on $M_r$ and the rest-frame $g - r$ color following the prescription provided in Johnson et al. (2015). The relation is calibrated for a Chabrier (2003) initial mass function with typical uncertainties in $M_{\text{star}}$ of less than 0.15 dex (see Johnson et al. 2015 for a detailed discussion). While the three line-emitters, G1, G2, & G3, are not detected in the DECaLS images, the MUSE spectra display blue continua. We adopt the blue branch from Johnson et al. (2015), when inferring $M_{\text{star}}$ for these galaxies. For the remaining member galaxies, we estimate $M_{\text{star}}$ based on the rest-frame $g - r$ color computed from available DECaLS photometry. Independent $M_{\text{star}}$ estimates using the FAST code (Kriek et al. 2009) are also available for objects observed in the MUSE frame (see Segers et al. 2018). Comparisons between our $M_{\text{star}}$ estimates and those from FAST show good agreements to within measurement uncertainties for all but one object. Galaxy G3 is the only exception with a FAST-estimated $M_{\text{star}}$ 0.6 dex higher than ours. But because G3 is merely 1.8$''$ from G4, object blending in MUSE data may impose additional systematic uncertainties in the $M_{\text{star}}$ measurement. In what follows, we describe the properties of individual group members.

G1 is an ultra faint dwarf galaxy found at $\theta = 8.2''$ and $z = 0.3313$, with corresponding projected distance $d = 39$ pkpc and line-of-sight velocity $\Delta v = +587$ km s$^{-1}$ from the LLS. The galaxy has $M_r = -14$, corresponding to 0.001$L_r$, and log $M_{\text{star}}/M_\odot = 6.9$. The optical spectrum of this galaxy is dominated by emission-line features, typical of a star-forming galaxy. We measure a rest-frame Hα.
Table 2. Intrinsic properties of galaxies in the vicinity of the LLS at $z = 0.3287$

| Galaxy | $d$ (pkpc) | $\Delta v$ (km s$^{-1}$) | $M_r$ | log $M_{star}/M_\odot$ | Type | $EW(\text{H}\alpha)$ (A) | SFR$^c$ (M$_\odot$ yr$^{-1}$) | ISM (O/H)$^d$ |
|--------|------------|----------------------|-------|----------------------|------|-------------------|---------------------|------------------|
| G1     | 0.3313     | $39 + 587$           | $-14.0$ | 6.9                  | SF   | $-59 \pm 10$      | 0.005               | $< 7.5^\circ$     |
| G2     | 0.3287     | 100                  | 0      | $-16.2$              | SF   | $-121.5 \pm 2.6$  | 0.10                | 7.8 $\pm 0.1$     |
| G3     | 0.3294     | 102                  | $+158$ | $-17.1$              | SF   | $-23.2 \pm 1.2$   | 0.03                | 7.5 $\pm 0.1$     |
| G4     | 0.3300     | 109                  | $+294$ | $-19.6$              | passive | 4.0 $\pm 0.6$   | $< 0.11$            | ...              |
| G5     | 0.3295     | 126                  | $+181$ | $-22.3$              | passive | 2.7 $\pm 0.2$   | $< 0.9$             | ...              |
| G6     | 0.3303     | 130                  | $+361$ | $-18.6$              | passive | 4.3 $\pm 1.0$   | $< 0.05$            | ...              |
| G7     | 0.3289     | 152                  | $+45$  | $-18.3$              | passive | 5.2 $\pm 1.0$   | $< 0.04$            | ...              |
| G8     | 0.3268     | 199                  | $-429$ | $-18.6$              | SF   | $-84.6 \pm 3.3$  | 0.30                | 8.3 $\pm 0.1$     |
| G9     | 0.3292     | 276                  | $+112$ | $-19.1$              | 9.7 passive | $-4.0 \pm 0.6$ | $< 0.05$            | ...              |
| G10    | 0.3293     | 316                  | $+135$ | $-18.7$              | 9.3 post SB  | $-10.2 \pm 1.0$ | 0.04                | ...              |
| G11    | 0.3294     | 354                  | $+158$ | $-19.1$              | 9.7 passive | $-11.7 \pm 1.2$ | $< 0.06$            | ...              |
| G12    | 0.3290     | 368                  | $+68$  | $-19.0$              | 9.6 passive | $< 2$            | $< 0.01$            | ...              |

$^a$At $z = 0.3$, star-forming galaxies have a characteristic rest-frame absolute r-band magnitude of $M_r = -21.3$ and passive galaxies have $M_r = -21.5$ (e.g., Cool et al. 2012).

$^b$Rest-frame H$\alpha$ equivalent width. Negative values represent emission, while positive values represent absorption.

$^c$For star-forming (SF) galaxies, SFR is estimated based on $L(\text{H}\alpha)$, while for passive galaxies a 2-$\sigma$ upper limit is estimated from the non-detection of [O II] $\lambda\lambda$3726, 3729.

$^d$For comparison, the oxygen abundance of the Sun is $12 + \log(O/H) = 8.69 \pm 0.05$ (Asplund et al. 2009).

$^e$Based on the mass-metallicity relation of local dwarf galaxies from Berg et al. (2012) with a dispersion of $\sigma_{(O/H)} = 0.15$ dex.

The equivalent width of $EW(\text{H}\alpha) = -59 \pm 10$ Å, a total line flux of $f(\text{H}\alpha) = (2.8 \pm 0.4) \times 10^{-18}$ erg s$^{-1}$ cm$^{-2}$, and a luminosity of $L(\text{H}\alpha) = (9.7 \pm 1.4) \times 10^{38}$ erg s$^{-1}$ which, following the calibration of Kennicutt & Evans (2012), leads to a star formation rate (SFR) of $(5 \pm 0.8) \times 10^{-3}$ M$_\odot$ yr$^{-1}$. To estimate the ISM gas-phase metallicity, we consider both the $N_\text{II}$ $\equiv \log [\text{N II}] \lambda 6585/\text{H}\alpha$ index and the $R_{32} \equiv ([\text{O II}] \lambda \lambda 3726, 3729 + [\text{O III}] \lambda \lambda 4959, 5007) / \text{H}\beta$ index. However, the expected location for the $[\text{N II}] \lambda 6585$ line is contaminated by strong OH lines. In addition, while the $[\text{O III}] \lambda \lambda 4959, 5007$ lines are detected at a high confidence level, the spectrum has insufficient quality for detecting H$\beta$ and $[\text{O II}] \lambda 3726, 3729$. Although we are unable to obtain a direct measurement of the gas-phase metallicity in the interstellar medium (ISM) of this object, we infer a gas-phase metallicity of $12 + \log(O/H) = 7.5 \pm 0.2$ based on its $M_{star}$ and the best-fit mass-metallicity relation of low-mass dwarf galaxies from Berg et al. (2012).

G3 is a faint dwarf galaxy found at $\theta = 21.6^\circ$ and $z = 0.3294$, with corresponding projected distance $d = 102$ pkpc and line-of-sight velocity $\Delta v = +158$ km s$^{-1}$ from the LLS. The galaxy has $M_r = -17$, corresponding to $0.02L_*$, and log $M_{star}/M_\odot = 8.1$. The optical spectrum of this galaxy is dominated by emission-line features, typical of a star-forming galaxy. We measure a rest-frame H$\alpha$ equivalent width of $EW(\text{H}\alpha) = -23.2 \pm 1.2$ Å, a total H$\alpha$ line flux of $f(\text{H}\alpha) = (1.7 \pm 0.1) \times 10^{-17}$ erg s$^{-1}$ cm$^{-2}$, and a luminosity of $L(\text{H}\alpha) = (5.9 \pm 0.3) \times 10^{38}$ erg s$^{-1}$, which leads to SFR = 0.032 $\pm 0.002$ M$_\odot$ yr$^{-1}$. Based on the non-detection of $[\text{NI}] \lambda 6585$, we infer a 2-$\sigma$ upper limit to the ISM gas-phase metallicity of $12 + \log(O/H) < 8.2$. Applying no extinction corrections based on the observed H$\alpha$/H$\beta$ ratio, we find based on the $R_{32}$ index an oxygen abundance of $12 + \log(O/H) = 7.5 \pm 0.1$ for the observed flux ratio of $R_{32} = 8.9 \pm 0.3$ with the error in gas metallicity dominated by the uncertainty in the $R_{32}$ calibration.

Galaxies G4, G5 (the LRG), G6, and G7 at $d = 109 - 152$ pkpc and $\Delta v = 45 - 361$ km s$^{-1}$ all exhibit strong absorption features such as Ca II H&K, G-band, Mg I triplet, and Balmer transitions, with no trace of emission lines. These galaxies have $M_r = -18.6 - 22.3$, corresponding to 0.07 - 2 $L_*$, and log $M_{star}/M_\odot = 9.6 - 11.1$. The rest-frame H$\alpha$ equivalent width ranges from $EW(\text{H}\alpha) = 2.7$ Å to 5.2 Å. The observed spectral features confirm that these are evolved galaxies with little/no ongoing star formation. We infer 2-$\sigma$ upper limits on the underlying SFR based on the absence of [O II] emission and the star formation calibrator of Kewley et al. (2004), assuming that no dust extinction correction is necessary for these quiescent galaxies. To gauge the chemical enrichment in these early-type galaxies, we estimate their stellar metallicities based on the Fe I line at 4686 Å and H$\gamma$ that are known to be sensitive to the underlying stellar age and metallicity. Following the definitions of these
indicates from Kuntschner & Davies (1998), we find that the C4668 equivalent width of these four galaxies ranges from 4.2 Å to 6.3 Å, and the Hγ equivalent width ranges from -6.8 Å to -3.0 Å, leading to a mean stellar metallicity that exceeds solar and a mean stellar age of ≳ 2 Gyr for these galaxies (see Figure 2 of Kuntschner & Davies 1998).

G8 is a star-forming dwarf galaxy found at θ = 42.1′′ and z = 0.3268, with corresponding projected distance d = 199 pkpc and line-of-sight velocity ∆v = -429 km s^{-1} from the LLS. The galaxy has M_r = -18.6, corresponding to 0.09 L_*, and log M_{star}/M_⊙ = 8.7. The optical spectrum of this galaxy exhibits strong emission-line features, typical of a star-forming galaxy. We measure a rest-frame Hα equivalent width of EW(Hα) = -84.6 ± 3.3 Å, a total Hα line flux of f(Hα) = (1.69 ± 0.07) × 10^{40} erg s^{-1} cm^{-2}, and a luminosity of L(Hα) = (5.5 ± 0.2) × 10^{40} erg s^{-1}, which leads to SFR = 3.0 ± 0.1 M_⊙ yr^{-1}. Based on the observed [N II] 6584/58 λ/λ 6564 ratio, we infer an ISM gas-phase metallicity of 12 + log(O/H) = 8.3 ± 0.1, ≈ 50% solar.

Galaxies G9 and G11 at d = 276 and 354 pkpc and Δv = +112 and +158 km s^{-1} both exhibit strong absorption features such as Ca II H,K, G-band, Mg I triplet, typical of a quiescent galaxy. At the same time, the spectra also display Hα and strong [N II] λ 6585 in emission, resembling nearby LINER-like galaxies (e.g., Sarzi et al. 2006; Yan et al. 2006). We measure a rest-frame Hα equivalent width of EW(Hα) = -4.0 ± 0.6 Å and EW([N II] λ 6585) = -3.4 ± 0.7 Å for G9 and EW(Hα) = -11.7 ± 1.2 Å and EW([N II] λ 6585) = -7.1 ± 1.9 Å for G11. These two galaxies have M_r ≈ -19.1, corresponding to 0.1 L_*, and log M_{star}/M_⊙ ≈ 9.7. Given the likely presence of additional ionizing sources that generated the emission features observed in the galaxy, we infer an upper limit on the underlying SFR of SFR < 0.02 M_⊙ yr^{-1} for G9 and SFR < 0.06 M_⊙ yr^{-1} for G11 based on the observed Hα line flux.

G10 is a post-starburst galaxy at θ = 66.6′′ and z = 0.3293, with corresponding projected distance d = 316 pkpc and line-of-sight velocity ∆v = +135 km s^{-1} from the LLS. The optical spectrum of this galaxy exhibits a combination of strong Ca II H,K and the Balmer absorption series, and weak emission features. The galaxy has M_r = -18.7, corresponding to 0.09 L_*, and log M_{star}/M_⊙ = 9.3. We measure a rest-frame Hα equivalent width of EW(Hα) = -10.2 ± 1.0 Å after correcting for stellar absorption, and find a corresponding total Hα line flux of f(Hα) = (2.2 ± 0.2) × 10^{-17} erg s^{-1} cm^{-2}, and a luminosity of L(Hα) = (7.2 ± 0.7) × 10^{40} erg s^{-1}, which leads to SFR = 0.04 ± 0.004 M_⊙ yr^{-1}. The spectrum does not have sufficient quality for placing a sensitive constraint for the associated [N II] lines. Based on the non-detection of [N II] λ 6585, we infer a 2-σ upper limit to the ISM gas-phase metallicity of 12 + log(O/H) < 8.6.

G12 is another quiescent galaxy at d = 386 pkpc and ∆v = +68 km s^{-1} with strong absorption features such as Ca II H,K, G-band, and Mg I triplet and no trace of emission lines. This galaxy has M_r ≈ -19, corresponding to 0.1 L_*, and log M_{star}/M_⊙ ≈ 9.6. We infer an upper limit on the underlying SFR of SFR < 0.01 M_⊙ yr^{-1} based on the absence of Hα line.

We summarize the properties of all 12 galaxies in Table 2, which lists the redshift z, projected distance d, line-of-sight velocity offset from the LLS ∆v, rest-frame r-band magnitude M_r, stellar mass M_{star}; galaxy type (star-forming versus passive), rest-frame Hα equivalent width EW(Hα), star formation rate SFR, and ISM gas-phase metallicity in columns (2) through (10). The extracted optical spectra of galaxies are also presented in Figure 4, along with the 1-σ error spectra.

4 DISCUSSION AND CONCLUSIONS

The analysis presented in § 3 demonstrates that combining deep HST images, MUSE observations, and wide-field survey data enables an unprecedented, ultra-deep view of the galactic environment of a chemically-pristine LLS at z = 0.33. Previous efforts in characterizing the galactic environment of strong Hz absorbers at z < 1 include the identification of a gas-rich galaxy group near a damped Lyα absorber (DLA) of log N(HI)/cm^{-2} = 21.7 ± 0.1 and ≈ 12% solar metallicity at z = 0.313 (Chen & Lanzetta 2003; Kacprzak et al. 2010), the discovery of a metal-poor ([O II] = -1.6 ± 0.1) strong LLS of log N(HII)/cm^{-2} = 19.3 at z = 0.0063 in the outskirts of the Virgo cluster (Tripp et al. 2005), and a star-forming galaxy at d = 54 kpc from a strong LLS of log N(HII)/cm^{-2} = 19.1 and ≳ 10% solar metallicity at z = 0.78 (Rahmani et al. 2018). In the first case, the metallicity of the DLA was found to be similar to the ISM metallicity in some of the group members, indicating that the DLA originates in tidal debris in the group environment. In the second case, the LLS was found to be associated with the NGC 4261 group with the nearest galaxy being a star-forming galaxy of 0.25 L_*. At d = 86 kpc from the absorber, and the metal-poor LLS was attributed to the ISM removed from dwarf satellites (however, see Chengalur et al. 2015 for more discussions). In the third case, the LLS was moderately enriched and was attributed to galactic winds from the disk galaxy. In all cases, the galaxy survey data are too incomplete to place stringent constraints for the possible presence of ultra-faint dwarf satellites.

Our spectroscopic survey in the inner 150 pkpc radius of the QSO sightline reaches a 100% completeness level for galaxies of luminosity > 0.02 L_*, which allows for the redshift of the absorber, and maintains a 50% completeness level for galaxies as faint as 0.007 L_*. Beyond d = 150 kpc, the LDSS3 survey reaches > 70% completeness for galaxies of > 0.05 L_*. A group of 12 galaxies are found at d ≤ 400 pkpc and |∆v| < 600 km s^{-1} of the optically-thick absorber, with intrinsic luminosity ranging from 0.001 L_*/2 L_*, and a corresponding stellar mass range of M_{star} ≈ 10^{-11} M_⊙. The wide-area LDSS3 survey covered an area out to d ≈ 1 Mpc in projected distance from the QSO sightline, but it did not uncover additional galaxies associated with the galaxy 'group' at d > 400 pkpc.

The group of 12 galaxies in the vicinity of the LLS contains a total stellar mass of M_{star}(total) = 1.6 × 10^{11} M_⊙, ≈ 80% of which resides in the LRG. Considering all 12 galaxies together, we calculate the location of the projected center of mass of the galaxy ‘group’ and find that it is located at (+12.3′′, +21.6′′) from the QSO sightline. The corresponding projected distance of the ‘group’ is therefore d_{group} = 118 pkpc and the M_{star}-weighted line-of-sight velocity offset is ∆v_{group} = 181 km s^{-1} between the galaxy ‘group’ and the
Figure 4. Optical spectra of 12 galaxies found in the vicinity of the chemically-pristine Lyman limit absorber at $z = 0.3287$ (Papers I&II) with increasing projected distance from top to bottom. The corresponding 1-$\sigma$ error spectra are shown in cyan. Prominent spectral features are highlighted in red dotted lines, marked with the corresponding line identifications. The best-fit redshift and the corresponding projected distance ($d$) and rest-frame absolute $r$-band magnitude ($M_r$) are listed on the right. The spectral panels are organized with increasing projected distances from top to bottom. Galaxy spectra of G1 through G7 are from MUSE, while the remaining five are from the LDSS3 observations. All three galaxies at $d \lesssim 100$ pkpc are emission-line dominated faint galaxies ($< 0.02 L_*$), while the LRG (G5) remains to be the most dominant galaxy (contributing $\approx 80\%$ in the total mass) in this galaxy ‘group’.

Chen et al.

MNRAS 000, 1–13 (2017)
LLS. We also calculate a line-of-sight velocity dispersion of σ_{group} = 230 km s^{-1} between these 12 galaxies, implying a dynamical mass of M_{dyn} ≈ 2 \times 10^{13} M_{\odot}, consistent with the LRG halo mass inferred from the mean stellar mass to halo mass relation (e.g., Behroozi et al. 2013). It is clear that the LRG (G5) dominates the mass of the ‘group’ and that the line-of-sight velocity offset between the LLS and the LRG is within the bound of the halo velocity dispersion.

While our survey has uncovered three previously unknown galaxies at closer projected distances, d ≲ 100 pkpc, from the LLS to the massive LRG, all three galaxies combined contribute to no more than 0.2% of M_{star} seen in the LRG at z = 126 pkpc. In addition, while the three group members at d ≲ 100 pkpc are faint with intrinsic luminosity < 0.02 L_*, the inferred ISM gas phase metallicity of > 0.06 solar is still more than 10 times higher than the 95% upper limit derived for the LLS. In principle, effective mixing between chemically-enriched ISM ejecta and chemically-pristine IGM can result in a significant dilution in the metallicity of the LLS (e.g., Schaye et al. 2007). To evaluate the effect of chemical dilution, we first recall the definition of gas metallicity as the mass fraction of heavy elements, Z_{gas} ≡ m(Z)/m_{gas}. The mean gas metallicity of a LLS originating in a cloud of well-mixed ISM and IGM is therefore

\[
(Z)_{\text{LLS}} = \frac{Z_{\text{ISM}} + m_{\text{ISM}} + Z_{\text{IGM}} + m_{\text{IGM}}}{m_{\text{ISM}} + m_{\text{IGM}}},
\]

where m_{ISM} and m_{IGM} represent the total mass of interstellar and intergalactic gas in the LLS, and the ISM metallicity is expected to be much greater than what is seen in the IGM, Z_{\text{ISM}} ≫ Z_{\text{IGM}}.

Following Equation (1), it is immediately clear that if ISM ejecta dominates in mass over accreted IGM in the LLS, m_{ISM} ≫ m_{IGM}, then \langle Z \rangle_{\text{LLS}} ≈ Z_{\text{ISM}}. If both ISM ejecta and IGM contribute comparably to the LLS, m_{ISM} ≈ m_{IGM}, then \langle Z \rangle_{\text{LLS}} ≈ 1/2 Z_{\text{ISM}}. However, if metal-poor IGM dominates in the LLS, m_{IGM} ≫ m_{ISM}, then \langle Z \rangle_{\text{LLS}} ≪ Z_{\text{ISM}} which is what we see for the LLS at z = 0.33.

Consequently, the observed disparity in the chemical enrichment level between the LLS and the group members has two important implications. First, it is unlikely that the LLS originates in ejecta from these faint galaxies either by stellar feedback or by ram-pressure stripping (cf. Whiting et al. 2006; Kaarnekrzuk et al. 2010; Gauthier et al. 2013; Belfiore et al. 2017). Observations of nearby low-mass galaxies have established a mass-metallicity relation of 12 + log(O/H) = (5.61 ± 0.24) + (0.29 ± 0.03) log M_{star}/M_\odot with a scatter of σ(O/H) = 0.15 dex over a mass range of log M_{star}/M_\odot = 7 – 9.5 (Berg et al. 2012), similar to the mass range of the low-mass galaxies found near the LLS. At log M_{star}/M_\odot ≈ 7, the ISM metallicity is ≈ 10% solar following this mean relation. Recently, Hsyu et al. (2018) extended this effort to lower mass with a minimum mass of log M_{star}/M_\odot = 5.2. The mass-metallicity relation of these ultra-low mass dwarfs is in good agreement with the best-fit relation of Berg et al., and remains at > 2.5% solar for the lowest-mass galaxy of log M_{star}/M_\odot = 5.2 in their sample. With a lack of metallicity gradient observed in low-mass galaxies (e.g., Pérez-Montero et al. 2016; Belfiore et al. 2017), the ISM metallicity in the outskirts of these dwarf galaxies is likely at a similar level, still more than a factor of four higher than the LLS. Condensed cool clumps from the hot halo are also an unlikely explanation (cf. Gauthier & Chen 2011; Huang et al. 2016) under the expectation that gaseous halos around low-redshift elliptical galaxies are chemically enriched to solar or near solar metallicities (e.g., Mathews & Brighenti 2003; Mernier et al. 2017). Therefore, the LLS is likely to originate in infalling gas from the IGM in the LRG halo. Second, the detection of an extremely low-metallicity LLS in a massive quiescent halo at z = 0.33, among the most metal-poor LLS found at z < 1 (e.g., Ribaudo et al. 2011), also indicates that parts of the IGM near old and massive galaxies still remain chemically pristine through the not too distant past.

While accretion is necessary to sustain galaxy growth, direct observational evidence of gas accretion remains scarce (e.g., Heitsch & Putman 2009; Turner et al. 2017; see also Putman 2017 for a recent review). Numerical simulations have suggested that gas accretion proceeds along the disk plane with a limited sky covering fraction of ≲ 10% (e.g., Faucher-Giguère & Keres 2011), making frequent detections challenging. Although the study presented here focuses on a single LLS, the implication is broad. Recall that the LLS is one of the seven optically-thick absorbers uncovered from the COS-LRG program, which was designed to for a systematic survey of the CGM at d < 160 pkpc of 16 random LRGs (Paper I). Three of these optically-thick absorbers are metal-poor with gas metallicity < 3% solar (Paper II). Attributing these chemically-pristine LLS to cold streams accreted from the IGM would imply a mean covering fraction of (k) ≈ 0.18 for these cold streams, which is significantly higher than the expectation of few percents for massive halos at low redshifts from cosmological simulations (cf. Halen et al. 2017). A larger sample of LLS with deep galaxy survey data available will be helpful to better quantify the incidence of IGM accretion galactic halos.

ACKNOWLEDGEMENTS

HWC and FSZ acknowledge partial support from HST-GO-14145.01A and NSF AST-1715692 grants. SDJ is supported by a NASA Hubble Fellowship (HST-HF2-51375.001-A). SC gratefully acknowledges support from Swiss National Science Foundation grant PP00P2_163824. This work is based on observations made with ESO Telescopes at the Paranal Observatory under programme ID 095.A-0200(A), data gathered with the 6.5m Magellan Telescopes located at Las Campanas Observatory, and imaging data gathered under the GO-14660 program using the NASA/ESA Hubble Space Telescope operated by the Space Telescope Science Institute and the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555. We acknowledge the use of DECaLS survey products.
