Abstract. A well-known potential dark matter signature is emission of GeV–TeV neutrinos from annihilation of neutralinos gravitationally bound to massive objects. We present results from recent searches for high energy neutrino emission from the Sun with AMANDA, in all cases revealing no significant excess. We show limits on both neutralino-induced muon flux from the Sun and neutralino-nucleon cross section, comparing them with recent IceCube results. Particularly, our limits on spin-dependent cross section are much better than those obtained in direct detection experiments, allowing AMANDA and other neutrino telescopes to search a complementary portion of MSSM parameter space.

Keywords: AMANDA WIMP Neutralino

I. INTRODUCTION

Weakly interacting massive particles (WIMPs) with electroweak scale masses are currently a favored explanation of the missing mass in the universe. Such particles must either be stable or have a lifetime comparable to the age of the universe, and they would interact with baryonic matter gravitationally and through weak interactions. The minimal supersymmetric standard model (MSSM) provides a natural candidate, the lightest neutralino [11]. A large range of potential neutralino masses exists, with a lower bound on the mass of the lightest neutralino of 47 GeV imposed by accelerator-based analyses [2], while predictions based on the inferred dark matter density suggest masses up to several TeV [3].

Searches for neutralino dark matter include direct searches for nuclear recoils from weak interaction of neutralinos with matter [4, 5] and indirect searches for standard model particles produced by neutralino annihilation. Particularly, a fraction of neutralinos interacting with massive objects would become gravitationally bound and accumulate in the center. If neutralinos comprise dark matter, enough should accumulate and annihilate to produce an observable neutrino flux. Searches for a high energy neutrino beam from the center of the Earth [6] and the Sun [7, 8, 9, 10, 11] have yielded negative results. Observations of a cosmic ray electron-positron excess by ATIC [12], PPB-BETS [13], Fermi [14], and HESS [15], along with the anomalous cosmic ray positron fraction reported by PAMELA [16], could be interpreted as an indirect signal of dark matter annihilation in our galaxy [17].

Here we present searches for a flux of GeV–TeV neutrinos from the Sun using AMANDA. We improve on the sensitivity of the previous AMANDA analysis [11] significantly and extend the latest results from IceCube [17] to lower neutralino masses. We observe no neutralino annihilation signal and report limits on the neutrino-induced muon flux from the Sun and the resulting limits on neutralino-proton spin-dependent cross section.

II. NEUTRINO DETECTION WITH AMANDA

The detection of neutrino fluxes above ~ 50 GeV is a major goal of the Antarctic Muon And Neutrino Detector Array (AMANDA). AMANDA consists of 677 optical modules embedded 1500 m to 2000 m deep in the ice sheet at the South Pole, arranged in 19 vertical strings and occupying a volume of ~ 0.02 km³. Each module contains a 20 cm diameter photomultiplier tube (PMT) optically coupled to an outer glass pressure sphere. PMT pulses (“hits”) from incident Cherenkov light are propagated to surface electronics and are recorded as an event when 6–7 hits on any one string or 24 total hits occur within 2.5 µs. The vast majority of the O(10⁹) events recorded each year are downgoing muons produced by cosmic ray air showers in the atmosphere above the South Pole. Relativistic charged leptons produced near the detector via charged-current neutrino interactions similarly trigger the detector, with several thousand atmospheric neutrino induced muon events recorded per year. The hit leading edge times, along with the known AMANDA geometry and ice properties [18], allow reconstruction of muon tracks with median accuracy 1.5° – 2.5°, dependent on zenith angle.

AMANDA operated in standalone from 2000–2006 and is currently a subdetector of the much larger (~ km³) IceCube Neutrino Observatory [19], scheduled for completion in 2011. The optical module density of AMANDA is much higher than that of IceCube, making AMANDA more efficient for low-energy muons (≤ 300 GeV) which emit less Cherenkov light.

III. DATA SELECTION AND METHODS

We describe two separate searches for Solar neutralinos in this proceeding. First, we present a search using a large data sample from 2000–2006 prepared for a high energy extraterrestrial point source search [20, 21]. We also present a search using data from 2001–2003, optimized to retain low energy events [22]. Both analyses are done in two stages; first, neutrino...
induced muon events are isolated from the much larger background of downgoing muons, then a search method is used to test for an excess at the location of the Sun.

A. Data Selection

While the Sun is above the horizon, neutrino-induced muons from the Sun are masked by the much larger background of downgoing cosmic ray muons; thus, we select data during the period when the Sun is below the horizon (Mar. 21 – Sept. 21), resulting in 953 days live-time from 2000–2006 and 384 days from 2001–2003. In both analyses, neutrino events are isolated by selecting well reconstructed upgoing muon tracks. Events are first reconstructed with fast pattern matching algorithms, and events with zenith angles $\theta < 80^\circ$ ($\theta < 70^\circ$ for the 2001–2003 analysis) are discarded, eliminating the vast majority of downgoing muons. The remaining events are reconstructed with a more computationally intensive maximum-likelihood reconstruction [23] accurate to 1.5$^\circ$ – 2.5$^\circ$, and again events with $\theta < 80^\circ$ are discarded.

$\mathcal{O}(10^6)$ misreconstructed downgoing muon events remain per year, and these are reduced by cuts on track quality parameters such as track angular uncertainty [24], the smoothness (evenness) of hits along the track [23], and the likelihood difference between the maximum-likelihood track and a forced downgoing likelihood fit using the zenith distribution of downgoing muons as a prior [23]. For the 2000–2006 analysis, 6595 events remain after quality cuts, dominantly atmospheric neutrinos [20], reduced to 4665 events by requiring dates when the Sun is below the horizon. Zenith distributions from 2000–2006 are shown in figure 1.

The selection is more efficient than the 2000–2006 analysis, with 21% of signal retained for 5 TeV $W^+W^-$ channel, to 4% for 100 GeV, $bb$ channel. The 2001–2003 analysis additionally considers 50 GeV neutralino masses, with a signal efficiency of 1%–3%.

B. Search Method

Both analyses use maximum-likelihood methods [25] to search for an excess of events near the location of the Sun. The data is modeled as a mixture of $n_s$ signal events from the Sun and background events from both atmospheric neutrinos and misreconstructed downgoing muons. The signal likelihood for the $i$th event is

$$S_i = \frac{1}{2\pi\sigma_i^2}e^{-\frac{\psi_i^2}{2\sigma_i^2}},$$

where $\psi_i$ is the space angle difference between the event and the Sun, and $\sigma_i$ is the event angular uncertainty [24]. The background likelihood $B_i$ is obtained from the zenith distribution of off-source data. The full-data likelihood over all $N$ data events is

$$\mathcal{L} = P(Data|n_s) = \prod_{i=1}^{N} \left( \frac{n_s}{N} S_i + (1 - \frac{n_s}{N}) B_i \right)$$

![Fig. 1. Reconstructed zenith angles of data (circles) at trigger level, filter level (dashed), and final cut level (dash-dotted). The selection is more efficient than the 2000–2006 analysis, with 21% of signal retained for 5 TeV $W^+W^-$ channel, to 4% for 100 GeV, $bb$ channel. The 2001–2003 analysis additionally considers 50 GeV neutralino masses, with a signal efficiency of 1%–3%.](image-url)
and is numerically maximized to find the best fit event excess $n_x$. The likelihood ratio $-2 \log \frac{L(0)}{L(n_x)}$ is approximately $\chi^2$ distributed and provides a measure of significance. Event upper limits are set from this likelihood using the Feldman-Cousins unified construction [29].

C. Signal Simulation and Systematic Uncertainties

Neutrino energy distributions at Earth from neutralino annihilation in the Sun are generated by DarkSUSY [27]. For the 2000–2006 analysis, neutrino events are generated with ANIS [28], with muons propagated using WimpSimp [30], and muons are propagated with MCM.

Uncertainties in our signal simulation are dominated by uncertainties in optical module sensitivity and photon propagation in ice. These uncertainties are constrained by comparing the trigger rate of CORSIKA [31] down-going muon simulation using various hadronic models with the observed AMANDA trigger rate. The effect on signal prediction is measured by shifting the simulated optical module efficiency by these constraints and is 10% for $m_{\chi} = 5 \text{ TeV}$, $W^+W^-$ channel, to 21% for $m_{\chi} = 100 \text{ GeV}$, $b\bar{b}$ channel. Other sources of uncertainty include event selection (4%–8%) and uncertainty in neutrino mixing angles (5%). For the 2000–2006 analysis, uncertainties total 13%–24% and are included in the limit calculation using the method of Conrad et al. [32] as modified by Hill [33]. Uncertainties for 2001–2003 total 23%–38% and are included in the limits assuming the worst case.

IV. RESULTS

The search methods are applied to the final data, and both analyses reveal no significant excess of neutrino-induced muons from the direction of the Sun. A Sun-centered significance skymap from the 2000–2006 analysis (figure 2) shows a 0.8$\sigma$ deficit from the direction of the Sun. For the 2001–2003 analysis, a deficit of events is observed in classes A and C, and a small excess is seen in class B. Each excess or deficit is within the 1$\sigma$ range of background fluctuations.

Upper limits on the neutralino annihilation rate in the Sun are calculated from the event upper limit $\mu_0$ by

$$\Gamma_A = \frac{4\pi R^2 \rho_{\mu_0}}{N_A \rho T_L \nu_{eff}} \left( \int_0^{m_{\chi}} \sigma_{\chi N} \frac{dN_\mu}{dE} dE \right)^{-1},$$

where $R$ is the Earth-Sun radius, $N_A$ is the Avogadro constant, $\rho$ is the density of the detector medium, $T_L$ is the livetime, and $\sigma_{\chi N}$ is the neutrino-nucleon cross section. The muon neutrino energy spectrum $\frac{dN_\mu}{dE}$ for a given annihilation channel is obtained from DarkSUSY and includes absorption and oscillation effects from transit through the Sun and to Earth. The energy-averaged effective volume $\nu_{eff}$ is obtained from simulation. Limits on muon flux are given by

$$\Phi_\mu = \frac{\Gamma_A}{4\pi R^2} \int_0^{m_{\chi}} \frac{dN_\mu}{dE} dE,$$

and limits on neutralino-proton cross section are calculated according to [34]. These quantities are tabulated in table I for the more restrictive of the two analyses. Muon flux limits, assuming a 1 GeV threshold on muon energy, and spin-dependent cross section limits are shown in figure 3 for both analyses.

V. DISCUSSION

These limits extend the latest IceCube limits to lower neutralino masses and are now beginning to exclude neutralino spin-dependent cross sections allowed by direct detection experiments (figure 3). A 1000-fold improvement over current direct-detection limits [4], [5] does not significantly constrain allowed spin-dependent cross sections; thus, neutrino telescopes will continue to observe a complementary portion of MSSM parameter space over the next several years. IceCube is currently operating with 59 strings and will contain 86 strings when complete in 2011. The DeepCore extension to IceCube [35],six strings with tighter string spacing (72 m), tighter optical module spacing (7 m), and higher PMT quantum efficiency, will be complete in 2010. DeepCore will significantly enhance the sensitivity of IceCube to low energy muons, extending the reach of IceCube to lower neutralino masses.
