Muon spin rotation ($\mu$SR) spectroscopy has been used to measure the effective size $r_0$ of the vortex cores in optimally doped YBa$_2$Cu$_3$O$_{6.95}$ as a function of temperature $T$ and magnetic field $H$ deep in the superconducting state. While $r_0$ at $H = 2$ T is close to 20 Å and consistent with that measured by STM at 6 T, we find a striking increase in $r_0$ at lower magnetic fields, where it approaches an extraordinarily large value of about 100 Å. This suggests that the average value of the superconducting coherence length $\xi_{ab}$ in cuprate superconductors may be much larger than previously thought at low magnetic fields in the vortex state.

# Expansion of the Vortex Cores

The vortex core in a type-II superconductor is a region in which the superconducting order parameter $\psi(r)$ is strongly suppressed. The size of the vortex core is therefore closely related to the coherence length $\xi$—which is the smallest length over which $\psi(r)$ can change appreciably. Some time ago Caroli et al. [1] predicted that a discrete spectrum of quasiparticle excitations existed within a radius $\xi$ of the vortex axis. An STM experiment on the conventional type-II superconductor NbSe$_2$ by Hess et al. [2] confirmed the existence of these localized states in the vortex core. Since then both $\mu$SR [3] and STM [4] measurements have shown that the vortex core size $r_0$ in NbSe$_2$ decreases with increasing magnetic field—in a manner which scales with the increased strength of the vortex-vortex interactions. These same techniques [3,4,5] have also shown that $r_0$ shrinks with decreasing temperature, as predicted by the so-called “Kramers-Pesch effect” [6].

The electronic structure of the vortex cores in the high-$T_c$ superconductors (HTSs) is less certain. Experiments performed on YBa$_2$Cu$_3$O$_{7-\delta}$ (YBCO) [7,8] and Nd$_{1.85}$Ce$_{0.15}$CuO$_{4-\delta}$ (NCCO) [9] seem to support the existence of a few bound quasiparticle states in the vortex core. On the other hand, no evidence of such localized states was found in a recent STM study of the vortex core in under and overdoped Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ (BSSCO) [10]. Instead the tunneling spectra in the vortex core resembled the pseudogap which forms at the Fermi surface in the normal state of this material. It should be noted that the vortex lattice studied in Ref. [10] was either not or consisted of randomly pinned pancake vortices.

It is now widely accepted that the order parameter in the hole-doped HTSs (which excludes NCCO) have a $d_{x^2-y^2}$-wave symmetry. Several authors have pointed out [10,11] that bound quasiparticle states are unlikely to exist in a vortex of a $d_{x^2-y^2}$-wave superconductor because of the nodes which are present in the energy gap function $\Delta_k = \Delta_0(\hat{k}_x^2-\hat{k}_y^2)$ along the directions $|\hat{k}_x| = |\hat{k}_y|$. One way of explaining experiments on HTSs which support localized states in the vortex core, is to introduce additional components into $\psi(r)$ (e.g. a $d_{xy}$-wave component [12]). However, there is currently no direct evidence for an order parameter of mixed symmetry in the bulk of HTSs.

In a previous study [11], we determined the size of the vortex cores in the underdoped compound...
YBa$_2$Cu$_3$O$_{6.60}$. The electronic structure of the cores in underdoped YBCO has yet to be investigated with STM—although one may anticipate a local density of states resembling the normal state pseudogap, as in underdoped BSCCO [1]. In Ref. [1] $r_0$ was found to change as a function of $T$ and $H$ in a manner similar to that observed in NbSe$_2$, but with a considerably weaker temperature dependence. Hayashi et al. [2] recently suggested that this may indicate that the quantum limit is established at a much higher temperature in YBa$_2$Cu$_3$O$_{6.60}$ because of the small value of $\xi$ relative to that in NbSe$_2$. Generally speaking, $\xi$ is considered to be “short” in the HTSs (e.g. $< 20$ Å) [3]. This is one of the primary features which distinguishes them from conventional superconductors. In YBa$_2$Cu$_3$O$_{6.60}$, $r_0$ was found to be as large as 80 Å at low magnetic fields, which suggests that $\xi$ is in excess of 20 Å. However, this is a phase with a $T_c$ of 60 K, so $\xi$ is expected to be somewhat larger than in a higher $T_c$ sample. Thus, it is of great interest to check the size and field dependence of $r_0$ in optimally doped YBa$_2$Cu$_3$O$_{6.95}$, with the maximum $T_c$ of 93 K. Unlike in underdoped YBCO, the formation of the pseudogap in YBa$_2$Cu$_3$O$_{6.95}$ appears to coincide with the superconducting gap at $T_c$. The STM study of the vortex core by Maggio-Aprile et al. [4] in near optimally-doped YBCO, clearly shows two peaks within a gap like structure—indicating the presence of bound quasiparticle states.

In this Letter we present $\mu$SR measurements of the effective vortex core size in YBa$_2$Cu$_3$O$_{6.95}$ as a function of temperature and magnetic field applied along the $c$ axis of the crystals. Our measurements of $r_0$ are shown to be consistent with the STM study of Ref. [4] at $H = 6$ T. Surprisingly, we find that at low fields $r_0$ increases to a comparatively large value of 100 Å. A simple interpretation of this result would be that the length scale over which the order parameter changes in the region of the vortex core (i.e. the definition of the coherence length as pertaining to the vortex core) is considerably larger than the nominal and accepted value of about 20 Å measured in high magnetic fields.

We report here measurements of $r_0$ in three different samples of YBa$_2$Cu$_3$O$_{6.95}$. The magnetic field distributions in two of these samples were previously recorded [5]. The first (TW1) was a mosaic of three crystals whereas the other (TW2) was a single crystal. All of these crystals contained twin boundaries and had transition temperatures of 93.2(0.25) K. We also report here measurements taken in TW2 after removing the twin boundaries. Detwinning was achieved by applying uniaxial stress to the crystal with the sample heated to no more than 250 °C in an oxygen atmosphere. Subsequent to the mechanical detwinning process, the crystal was reannealed to set the oxygen doping level. The $\mu$SR experiments were performed on the M15 and M20 surface beamlines at TRIUMF. Our experimental setup is described elsewhere [6].

Although $\mu$SR does not directly probe the electronic structure of the vortex cores, it does sample the distribution of local magnetic fields in the vicinity of the cores. The spin of an implanted muon precesses at a frequency which is directly proportional to the local magnetic field at the muon site. Since the local magnetic field rises to a maximum in the vortex cores where superconductivity is destroyed, $r_0$ is directly related to the high-field tail in the measured field distribution. The size of the core is not strictly defined however, because there is no sharp discontinuity in spatial quantities between a normal vortex core and the surrounding superconducting material. Here, as in our previous work [6,7], we define $r_0$ to be the radius about the vortex axis at which the supercurrent density $J_s(r)$ reaches its maximum value. This feature allows us to accurately monitor changes in the effective size of the vortex cores. The supercurrent density $J_s(r)$ is obtained from the field profile $B(r)$ through the Maxwell relation $J_s(r) = |\nabla \times B(r)|$. In fitting the measured muon spin precession signal, some modelling of $B(r)$ is required. However, to appreciate the accuracy of the present study it is important to realize that the $J_s(r)$ profile does not depend on the validity of the model assumed, since it is essentially the same for any function $B(r)$ which fits the data well.

As in Refs. [6,7], the local field due to the vortex lattice at any point in the $a$–$b$ plane was modelled with a theoretical field distribution generated from a Ginzburg-Landau (GL) model [20]

$$B(r) = B_0(1 - b^4) \sum_G e^{-iG \cdot r} \frac{u K_1(u)}{\lambda_{ab}^2 G^2},$$

where

$$u^2 = 2 \xi_{ab}^2 G^2 (1 + b^4)(1 - 2b)(1 - b^2),$$

$B_0$ is the average magnetic field, $G$ are the reciprocal lattice vectors, $b = B_0/B_c$, $\xi_{ab}$ is the GL coherence length and $K_1(u)$ is a modified Bessel function. We do not expect the conventional GL model to be valid deep in the superconducting state. However, this model gives a very good fit to the measured field distribution—which is all that is required to generate the corresponding $J_s(r)$ profile needed to determine $r_0$. The summation in Eq. (1) is taken over all reciprocal lattice vectors $G$ of a triangular vortex lattice. This assumption is reasonable, because for field-cooled samples the vortex lattice geometry at low $T$ is governed by the geometry of the lattice at the pinning temperature. We have shown previously [21] that the vortex lattice in our YBa$_2$Cu$_3$O$_{6.95}$ crystals is strongly pinned at low $T$ and remains so upon warming up to $T \approx 0.7 \ T_c$. The lattice in the detwinned crystal depins at similar high temperatures. In a $d_{x^2-y^2}$-wave superconductor, the vortex lattice is predicted to be nearly triangular at temperatures close to $T_c$ (e.g. see Ref. [22]). We note that even if the lattice is not triangular, a good fit still yields the appropriate $J_s(r)$ profile.

All of the data were fit in the time domain with a theoretical muon polarization function constructed from the field profile of Eq. (1). This was multiplied by a Gaussian
relaxation function $e^{-x^2/2}$ to account for any residual disorder in the vortex lattice and the contribution of the nuclear dipolar moments to the internal field distribution. The residual background signal was fit assuming a Gaussian broadened distribution of fields. The Fourier transform (FT) of the muon precession signal approximates the internal field distribution and resembles the predicted asymmetric lineshape for an ordered lattice of vortices. However, the FT suffers from noise and broadening effects associated with the finite number of events and limited time range, so that the data must be analyzed in the time domain.

Figure 1(a) shows the first 1.5 $\mu$s of a typical muon precession signal in YBa$_2$Cu$_3$O$_{6.95}$ displayed in a reference frame rotating at 3.3 MHz below the Larmor precession frequency of a free muon. The solid curve is a fit (actually performed over the first 6 $\mu$s) to the theoretical polarization function assuming $\xi_{ab} = 54$ Å, with all other fitting parameters unconstrained. The difference between this fit and the measured spectrum is shown in Fig. 1(b), compared to the same assuming $\xi_{ab} = 20$ Å. Note that the quality of the fit is most affected by a change in $\xi_{ab}$ at early time, where the amplitude of the signal originating from the vortex lattice is largest. The ratio of $\chi^2$ to the number of degrees of freedom (NDF) for fits assuming different values of $\xi_{ab}$ is shown in Fig. 2(a) for two different magnetic fields. Due to the high statistics of the measured field distribution (i.e. typically consist of $2 \times 10^7$ muon decay events), $\chi^2$/NDF is greater than one. Figure 2(b) shows that $\kappa = \lambda_{ab}/\xi_{ab}$ obtained from the same fits also depends on $H$.

Figure 3(a) shows the temperature dependence of $r_0$ at $H = 0.5$ T and 1.5 T in sample TW1. The error bars represent the statistical uncertainty in the fitted values of $\xi_{ab}$. Both sets of data show a slight decrease in $r_0$ with decreasing temperature which is essentially linear below 50K. The strength of the term linear in the case of NbSe$_2$ is comparable to that previously reported in YBa$_2$Cu$_3$O$_{6.60}$ [13], which indicates that thermal vibrations are an unlikely source of the observed behaviour. On the other hand, this linear term is considerably weaker than in NbSe$_2$, and the ratio $\lambda_{ab}/r_0$ is well described by relations linear in $H$, so that

$$r_0(H) = \frac{\lambda_{ab}(H)}{\lambda_{ab}(H)/r_0(H)} = r_0(0)[1 + \beta H/(1 + \gamma H)]$$

Recently the field dependence of $\lambda_{ab}$ has been attributed to both nonlinear and nonlocal effects associated with a $d_{x^2-y^2}$-wave order parameter [23] and does not strictly reflect the field dependence of the superfluid density. In sample TW1, which constitutes the most complete data set for YBa$_2$Cu$_3$O$_{6.95}$, $r_0(0) = 120.7$ Å, $\beta = 0.075$ T$^{-1}$ and $\gamma = 1.82$ T$^{-1}$. On the other hand, in the twinned YBa$_2$Cu$_3$O$_{6.60}$ sample of Ref. [12] we find that $r_0(0) = 156.3$ Å, $\beta = 0.094$ T$^{-1}$ and $\gamma = 1.77$ T$^{-1}$. The solid curves in Fig. 4 represent Eq. (2) with the corresponding values of $r_0(0)$, $\beta$ and $\gamma$. These extrapolations suggest that the shrinking of the vortex cores saturates at large $H$. Note that Eq. (2) can be written strictly in terms of the intervortex spacing $L$ (since $L \propto \sqrt{\gamma}$).

Maggio-Aprile et al. [1] attributed the two peaks observed in the spectrum for tunneling into a vortex core of YBCO at $T = 4.2$ K and $H = 6$ T, to the lowest bound quasiparticle energy level $E_{1/2} = 5.5$ meV. Using the formula $E_{1/2} = 2\mu\Delta_0/|E_F|$ from Ref. [1] and taking $\xi_{ab}$ at low $T$ to be equivalent to the BCS coherence length $\xi_0 = \hbar v_f/\pi\Delta_0$, gives $\xi_{ab} = (2\hbar^2/m_0\pi^2E_{1/2})^{1/2} \approx 17$ Å. This result ($\approx r_0$) is plotted in Fig. 4. The agreement with the extrapolated curve from our $\mu$SR measurements [23] is striking and raises the possibility that the vortex cores in YBa$_2$Cu$_3$O$_{6.95}$ are conventional-like (i.e. they contain localized quasiparticle states). Several theoretical studies (e.g. [14]) have suggested that bound states may arise from a second component in the order parameter, induced by spatial variations in the $d_{x^2-y^2}$-wave component in the vicinity of a vortex core. If this is the case, the core expansion will be accompanied by the formation of numerous bound states, which should be detectable by STM. Thus far, STM has not been used to probe the vortex structure at low magnetic fields in the HTSs.

In conclusion, we have observed a large increase in the size of the vortex cores in YBa$_2$Cu$_3$O$_{6.95}$ at low magnetic fields, similar to the behaviour reported in the conventional superconductor NbSe$_2$. The expansion of the cores appears to be a general property of superconductors in...
the vortex state. The agreement with STM measurements based on a conventional treatment of the vortex core in YBa$_2$Cu$_3$O$_{6.95}$, supports the existence of localized states in the core.
