Abstract

Background: C. burnetti, the causative agent of Q fever, is considered a potential threat as a biological weapon because of highly infectious and pathogenic. There was an outbreak of Q fever in Zhuhai, PR. China between December, 2018 and March 2019, although Zhuhai was not the endemic area of Q fever. 46 patients can be detected C. burnetti by metagenomic next-generation sequencing (mNGS). There are many similarities between acute Q fever and scrub typhus in clinical manifestations.

Methods: We analyze the differences of clinical manifestations and serological between 46 patients with acute Q fever and 100 patients with scrub typhus. The general information of patients including gender, age, basic disease, days from disease onset and clinical manifestations were evaluated.

Results: Their mean age of acute Q fever was 43.6±11.8 (ranging from 32 to 55 years old), younger than scrub typhus patients (53.9±12.7, ranging from 41 to 67 years old) (P<0.001). Males are more susceptible to C. burnetti. There were 45 males (97.8%) in acute Q fever patients and 59 males (59.0%) in scrub typhus patients (P<0.001). Compared with scrub typhus, patients with acute Q fever are more prone to present sore throat (P=0.003), abnormal liver function (P<0.001) and elevated levels of procalcitonin (P<0.001). Meanwhile, skin rash (P<0.001), eschar (P<0.001), lymphadenopathy (P<0.001), leukocytosis (P<0.001), thrombocytopenia (P=0.003), eosinophils reducing or disappearing (P=0.002) and pulmonary involvement on chest imaging (P=0.003) were more common in scrub typhus. There was significant difference between the two groups (P<0.001). Days from minocycline treatment to defervescence in acute Q fever (1.82±1.357, ranging from 0.5 to 3.2 days) were shorter than scrub typhus (2.85±2.801, ranging from 0.0 to 5.7 days) (P=0.008).

Conclusions: mNGS is helpful to early diagnosis of acute Q fever. Sex, age, serologic test and physical examination are important in the differentiation of acute Q fever from scrub typhus in Zhuhai, China.

1. Background

Q fever in human beings has been described in countries around the world, except New Zealand[1]. As we all know, Coxiella burnetii(C. burnetti), which causes Q fever, is a highly infectious agent and can resist extremes of temperature, pH, and desiccation, which is essential for survival in the harsh environment[1]. C. burnetti can be disseminated in an aerosolized form to cause chronic Q fever, sometimes fatal disease. Thus C. burnetti was considered a potential threat as a biological weapon in 1942 due to the highly infectious and pathogenic[2]. It is also reported that Russia fabricated Q fever as a biological weapon[2]. In addition, there were several Q fever outbreaks were reported in military personnel[2]. In the Border Army of Ali area of Tibet, there was a resurgence of Q fever in 1968[3]. However, Q fever has long been a neglected infectious disease so many aspects of the disease in China, including its diagnosis to clinical manifestations, are unknown, leading to misdiagnosis and missed diagnosis easily. Besides, only a few research laboratories are engaged in the research of Q fever[4]. There is an urgent need for a more detailed understanding of Q fever.
There were 46 patients diagnosed with acute Q fever by metagenomic next-generation sequencing (mNGS) in our hospital in Zhuhai, China. Metagenomics for clinical applications derives its roots from the use of core technology in the early 2000s[5]. By comparing the microbial database and analyzing the intelligent algorithm, this technique can obtain the species information of the suspected pathogenic microorganisms, which has great potential utility in the diagnosis of infectious disease. Some successes using this technology include the case of neuroleptospirosis in a 14-year-old critically ill boy with meningoencephalitis[6]. Also, mNGS was used for the clinical diagnosis of human infectious endophthalmitis caused by pseudorabies virus, as successful diagnosis prompted appropriate targeted antibiotic treatment and eventual recovery of the patient[7]. Compared with traditional molecular detection, mNGS has the characteristics of high throughput, low-volume sample, rapid and accurate[8], which can be used as a supplement to traditional detection methods.

Acute Q fever and scrub typhus belong to rickettsial diseases, and scrub typhus occurs with sporadic epidemics in Zhuhai. There are many similarities between acute Q fever and scrub typhus in clinical manifestations. Acute Q fever, a disease caused by the bacteria *C. burnetti*[9], presents various clinical manifestations such as fever, chills, headache, muscle aches and varying degrees of pneumonia and hepatitis[10]. Scrub typhus is a common zoonotic disease in humans, caused by *Orientia tsutsugamushi*(*O.tsutsugamushi*) infection[11]. Its major clinical feature is high fever, eschar or ulcer, lymphadenectasis and rash found at the inoculation site of the chigger bite[12, 13]. However, not all the patients of scrub typhus can be found the distinctive eschar. At present, acute Q fever is diagnosed through etiology test and serological examination, which include complement fixation test (CFT)[14], enzyme-linked-immunosorbent assay (ELISA)[15], indirect immune-fluorescence test (IFT)[16], cell culture[17], polymerase chain reaction(PCR)[18] and so on. The diagnosis of scrub typhus is always diagnosed based on serological tests and molecular assays[19], such as the indirect immunofluorescence assay (IFA)[20] and PCR[21]. However, the above methods are too expensive and complicated to achieve. Without the techniques for pathogenic detection, it is difficult to differentiate acute Q fever and scrub typhus in clinical practice. To assist early diagnosis for clinical, we analyze the differences of clinical manifestations and serological between patients with acute Q fever and scrub typhus.

2. Study Subject And Methods

2.1. Study subject

The medical records of patients diagnosed with acute Q fever and scrub typhus at The Fifth Affiliated Hospital of Sun Yat-sen University, which is a tertiary teaching hospital located in the Zhuhai region, from October 2014 to March 2019 were retrospectively reviewed. There were 46 acute Q fever patients whose blood samples can detect *C. burnetti* and 100 scrub typhus patients. The general information of patients including gender, age, basic disease, days from disease onset and clinical manifestations were evaluated.

2.2. Methods of mNGS
Serologic assessments using mNGS were performed in the contract laboratory of BGI. Blood samples were collected after hospital visit. And within 48 hours, the results could be sent to our OA from the contract laboratory of BGI after nucleic acid extraction, library construction and sequencing, data treatment and analysis. The methods of mNGS is as follows: 1) sample collection: blood samples were collected in accordance under strict aseptic procedures, snap frozen and stored at -80 °C before administering antibiotics treatment. 2) nucleic acid extraction: 0.6 ml plasma was obtained after centrifugation at 2000 g for 10 min and again centrifuged at 16000 g for 10 min. After two centrifugations, 0.3 ml supernatant was collected, which used for nucleic acid extraction with the TIANamp Micro DNA Kit (DP316, Tiangen Biotech, Beijing, China). 3) library construction and sequencing: the DNA libraries were constructed through end repair, end-repaired adapter added overnight and amplification by PCR. 4) data treatment and analysis: in order to generate high-quality sequencing data, the raw data was initially screened to remove low quality reads and shorter reads. To eliminate influence from human sequences, sequence data were mapped against the human reference genome (hg19) with the Burrows-Wheeler Aligner, formidable alignment tool. Finally, the remaining data were aligned to Microbial Genome Database, which includes bacteria, viruses, fungi, and protozoa to distinguish the pathogenic sequences.

2.3. The inclusion criteria of acute Q fever and scrub typhus

Acute Q fever was considered positive when at least 1 read was mapped to either the species or genus level due to the difficulty of DNA extraction, standard procedures and a low possibility for contamination. 46 patients whose blood samples can detect *C. burnetti*, were diagnosed with acute Q fever by mNGS.

The diagnosis of scrub typhus is based on the Technical Guides for Prevention and Control of Scrub Typhus by the Chinese Center for Disease Control and Prevention. The clinical diagnosis was mainly based on some of the following clinical features and signs: 1) Epidemiological exposure history within 3 weeks prior to the onset during the epidemic season, 2) fever, 3) lymphadenectasis, 4) skin rash, and 5) specific eschar or ulcer. Clinically confirmed cases are defined by meeting at least following criteria ‘1, 2, 3 and 5’or ‘1, 2, 4 and 5’after excluding other diseases with similar clinical manifestations.

2.4. Statistical Analysis

T test was used for continuous variables of the normal distribution, and non-parametric test was used for variables of non-normal distribution. Chi-square test or Fisher’s exact test was used for categorical variables. All statistical analyses were done using the Statistical Package for the Social Sciences (SPSS) for Windows, version 20 (IBM Corp., Armonk, NY, USA). *P* < 0.05 was considered statistically significant.

3. Results

3.1. The results of mNGS in acute Q fever

The mNGS testing results of 46 acute Q fever patients were shown in Fig. 1. According to Fig. 1, we can see that all 46 patients can be detected *C. burnetti*, which sequences number ranged from 2 to 824.
3.2. Acute Q fever and scrub typhus fever in epidemiology

There was an outbreak of Q fever between December and March, the maximum number occurred during January followed by February (Fig. 2). There were 30 patients were diagnosed as having acute Q fever in January. Besides, our study results demonstrate that the temporal distribution of reported scrub typhus cases followed a bimodal seasonal pattern characterized by two yearly peaks observed between May and December. We can see that the number of scrub typhus cases demonstrated a large peak in May or June, and then revealed another large peak in October with a continuous decrease thereafter. Scrub typhus cases were diagnosed in all months tested except January and April. However, acute Q fever cases only occurred from November to March during the research period.

3.3. Differences in clinical characteristics and complication between cases of acute Q fever and scrub typhus

The mean age of patients with acute Q fever was 43.6 ± 11.8 (ranging from 32 to 55 years old), younger than scrub typhus patients (53.9 ± 12.7, ranging from 41 to 67 years old) \((P< 0.001)\). Males are more susceptible to \(C. burnetti\). There were 45 males (97.8%) in acute Q fever patients and 59 males (59.0%) in scrub typhus patients \((P< 0.001)\). Fatty liver was more common in acute Q fever (47.7% vs 16.0%, \(P= 0.001\)). There was no difference between the two groups in the following basic disease: hypertensive disease, diabetes, coronary heart disease, chronic obstructive pulmonary disease, hepatitis B, pulmonary tuberculosis, malignancy, and dyslipidemia. \((P> 0.05)\) (Table 1).
Both acute Q fever and scrub typhus presented high fever. Their mean temperature of acute Q fever was 39.6 ± 0.42°C (ranging from 39.18 to 40.02°C), higher than scrub typhus patients (39.39 ± 0.65°C,
ranging from 38.7 to 40.04°C \((P = 0.044)\). Compared with acute Q fever patients, eschar \((P < 0.001)\), skin rash \((P < 0.001)\), lymphadenopathy \((P < 0.001)\), were more common in scrub typhus patients. However, there is no difference in chill, headache, muscle aches, fatigue, cough or poor appetite between the two groups. \((P \geq 0.05)\). It is noteworthy that patients with acute Q fever are more prone to present sore throat \((P = 0.003)\) than patients with scrub typhus (Table 2).

### Table 2
Differences in clinical symptoms and signs of acute Q fever and scrub typhus

|                      | Acute Q fever \(N = 46\) | Scrub typhus \(N = 100\) | \(P\) value | OR (95%CI) |
|----------------------|---------------------------|---------------------------|-------------|------------|
| Mean temperature ± SD| 39.57 ± 0.42              | 39.39 ± 0.65              | 0.044       | -0.359(-0.005) |
| Eschar               | 0(0.00)                   | 100(100.00)               | 0.000       | NA         |

| digestive tractemorrhage| 0(0)                   | 1(1.00)                | 1.000   | NA         |

ARDS = Acute Respiratory Distress Syndrome; GBS = Guillain-Barre syndrome; NA = not available; \(^a\): acute Q fever n = 45, scrub typhus n = 89.

3.4. Differences in laboratory detection between cases of acute Q fever and scrub typhus

Compared with scrub typhus patients, acute Q fever patients were more likely to show up normal white blood cell counts\((P < 0.001)\), elevated alanine aminotransferase (ALT) > 100U/L \((P = 0.002)\), \(\gamma\)-glutamine transferase \((\gamma\text{-GT}) > 60U/L \((P = 0.025)\), procalcitonin (PCT) > 0.5 ng/ml \((P < 0.001)\) than scrub typhus. However, there were more scrub typhus patients had leukocytosis\((P < 0.001)\), thrombocytopenia \((P = 0.003)\), eosinophils reducing or disappearing \((P = 0.002)\) than acute Q fever patients. In addition, there were no differences between the two subgroups in alanine aminotransferase (AST) range.

3.5. Response to minocycline treatment in cases of acute Q fever and scrub typhus

There was a significant difference between acute Q fever and scrub typhus in terms of response to minocycline treatment. Days from minocycline treatment to defervescence in acute Q fever \((1.82 \pm 1.36, \text{ranging from 0.46 to 3.18 days})\) were shorter than scrub typhus \((2.85 \pm 2.80, \text{ranging from 0.05 to 5.65 days})\) \((P = 0.008)\). The total hospital day of acute Q fever was \(5.33 \pm 2.73\) \((\text{ranging from 2.60 to 8.06})\).
days), shorter than scrub typhus patients (8.93 ± 5.46, ranging from 3.47 to 14.39 days) (P < 0.001) (Table 5).

Table 5
Response to minocycline treatment in cases of acute Q fever and scrub typhus.

4. Discussion

Our research shows that an outbreak of human Q fever occurred in Zhuhai. The main source of infection for Q fever was infected livestock, including sheep, cattle and goats[1]. When animals were infected with Coxiella burnetii, most of them have no obvious symptoms. Thus the infected animals can spread the C. burnetii when they give birth or were slaughtered. Relevant research shows that wind can carry the C. burnetii for miles[22]. People may get sick when they help animals give birth or breathe in the dust mixed with C. burnetii. Many cases illustrate people may get sick although low respiratory infective dose. However Q fever is frequently viewed as an unimportant disease because the symptoms are non-specific. The majority of patients in this study is male. Past research revealed that male acute Q fever patients evidently seem more at risk for direct C. burnetii than female[2, 23]. Unfortunately, misdiagnosis of acute Q fever and other febrile diseases is frequent because symptoms are often vague and nonspecific. Once infected, the soldier may develop several symptoms that, if misdiagnosed and spread, can cause a significant impact on the entire barracks[24]. Furthermore, Q fever is not a reportable disease and probably largely misdiagnosed on account of lack of diagnostic technique in China. As mentioned above, Q fever manifests in acute form, causing flu-like symptoms such as fever, headache, muscle aches, and chills, leading to misdiagnosis. If an appropriate antibiotic is not timely administered, acute Q fever can become chronic Q fever, which leads to low quality of life or even death. It is time to pay more attention to
Q fever. In this study, we used mNGS of a blood sample from the patient and detected *C. burnetti*, allowing us to diagnose acute Q fever. Figure 1 shows that *C. burnetti* can be detected by mNGS. Once the infection caused by *C. burnetti* had been diagnosed, doctors put them on minocycline as clinical empirical therapy. Surprisingly, the clinical symptoms were improved, which further strengthens our diagnosis is correct. It proves the issue that mNGS is helpful to the early diagnosis of acute Q fever. It is worth noting that mNGS, which is independent of traditional microbial cultivation and direct sequencing, is a rapid and objective assay to detect various pathogens in clinical samples (viruses, bacteria, fungi, and parasites)[25]. Also, mNGS can greatly reduce the detection time, providing the results less than 48 hours, and avoid the impact of culture conditions and antimicrobial use, which is especially suitable for the diagnosis of critically ill and incurable diseases[26–28]. There is no bias in mNGS, because no primer and nucleic acid were used in mNGS, improving the diagnosis of infectious diseases. In this study, we used mNGS to explore pathogens and were able to cure the patient.

According to this study, the highest incidence of acute Q fever occurred in January and February, while the highest incidence of scrub typhus occurred in May to October, which conforms to the summer-autumn type in south China[29, 30]. However, there was a rare outbreak of Q fever in Zhuhai, P.R. China, which may be biased. Thus, we needed to increase the size of the population for our study.

45 patients of acute Q fever were male, and the mean age of acute Q fever was 45 years (range 32–55), with a male-to-female ratio of 97.8%. However, only 59.0% patients of scrub typhus were male. This is supported by the literature that men are at higher risk of infection by *C. burnetti* than women[31]. Some studies have found the protective effects of estrogen against *C. burnetti* infection[32, 33], thus the symptoms were significantly more intense in men than in women. Also, the expression of the Per2 gene was increased in men with acute Q fever but not in women[34], which provides a reasonable explanation of the sexual discrepancy in Q fever. The younger they are, the more attention to their health conditions they pay, so that more of them consulted a physician and were diagnosed. Due to the timely treatment of minocycline, the patients of acute Q fever spent less time for the body temperature to return to normal.

There were no patients of acute Q fever exhibited eschar, skin rash and lymphadenopathy during the treatment process. On the contrary, in scrub typhus, eschar was found in 100.0% of the patients, skin rash in 40.0%, lymphadenopathy in 29.0%. Eschar, the characteristic manifestations by chigger bite, is found in 7%-97% patients[35]. Possible reasons for these discordant results that all the scrub typhus patients in this study show the characteristic eschar may be differences in diagnostic criteria. On the other hand, *O.tsutsugamushi* is transmitted to human through trombiculid bite[11, 12], and *C. burnetti* infection is transmitted by inhaling of aerosol through the respiratory tract[9, 36], which allows direct contact with arthropods to be avoided. Dendritic cells and monocytes may be the target cells of Orientia tsutsugamushi that can cause vasculitis and reticuloendothelial cell proliferation[37, 38], which may be cause skin rash and lymphadenopathy. In contrast, *C. burnetti* can invade the monocytes and macrophages, leading to granuloma formation[39–41]. Based on the above-mentioned findings, we emphasize the meticulous physical examination to find the characteristic presentation when a febrile patient comes.
Acute Q fever patients in many areas mainly presented with pneumonia rather than toxic hepatitis[42, 43]. However, our results showed that toxic hepatitis is the main form of presentation of Q fever in Zhuhai, with abnormal transaminase and γ-GT. Previous literature has shown that hepatitis rather than pneumonia is the predominant presentation of acute Q fever in southern Taiwan[44]. The exact reason for this is unknown. It is speculated that the symptom may be associated with the different C. burnetti genotypes in different regions[45]. Univariate analysis showed that leukocytosis, thrombocytopenia, eosinophils reducing or disappearing and pulmonary involvement on chest imaging were more common in scrub typhus.

Previous findings have shown that PCT is a trustful biomarker for bacterial infection, but not viral infection[46–48]. However, according to research by Rule,J.A. et al, PCT cannot be used for the diagnosis of bacterial infection in acute hepatic failure, whose level is associated with pathological severity[49]. The rise of PCT serum levels that could be used as a clinical indicator for judging the severity of scrub typhus, seems to be associated with high mortality of scrub typhus in ICU, but that prefer to a diagnosis of scrub typhus in other patients when PCT < 1.3 ng/ml[50, 51]. In this study, the PCT serum levels were significantly higher in acute Q fever than those in scrub typhus. On one hand, people infected with C. burnetti are more likely to suffer toxic hepatitis, which can lead to serum PCT levels increase by the release of more inflammatory factors. On the other hand, there are more non-severe patients in scrub typhus with mild histopathological changes in the liver.

5. Conclusions

In summary, this study suggests that more attention should be set on Q fever and mNGS may be a useful method for identity acute Q fever, especially without traditional culture methods. By compared the clinical features of the two diseases, we can conclude that sex, age, serologic test, and physical examination are important in the differentiation of acute Q fever from scrub typhus. Last but not least, careful physical examination, which can find the eschar, skin rash and lymphadenopathy plays an important role in differentiating acute Q fever and scrub typhus.

Abbreviations

C. burnetti
Coxiella burnetti; O. tsutsugamushi: Orientia tsutsugamushi; mNGS: Metagenomic next-generation sequencing; ELISA: Enzyme Linked Immunosorbent Assay; IFA: Indirect Immunofluorescence Assay; PCR: Polymerase Chain Reaction; WBC: White Blood Cell; NEU: Neutrophil; EOS: Eosinophils; PLT: Platelets; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; T-BIL: Total bilirubin; γ-GT: γ-glutamyl transpeptidase; ESR: Erythrocyte Sedimentation Rate; CRP: C-reactive protein; PCT: Procalcitonin; SCr: Serum Creatinine; ARDS
Acute Respiratory Distress Syndrome; GBS: Guillain-Barre syndrome.
Declarations

Ethics Statement and Informed Consent

This study was approved by the institutional review board of the Fifth Affiliated Hospital of Sun Yat-sen University (Zhuhai, P.R. China) (No.ZDWY[2020] Lunzi No. (K19-1)). Waiver of consent was obtained given the observational nature of the project.

Consent for publication

Not applicable.

Availability of data and materials

The datasets used and/or analysed during the current study are available from the corresponding author on reasonable request.

Competing interests

The authors declare that they have no competing interests.

Author Contributions

Jinyu Xia designed the study. Xi Liu and Ziliang Lin wrote the manuscript. Gongqi Chen, Hongqiong Zhu and Pengyuan He attended patients and provided clinical data. Mingxing Huang performed data analysis.

All authors read and approved the final version of the manuscript.
