Abstract

The border-collision normal form is a canonical form for two-dimensional, continuous maps comprised of two affine pieces. In this paper we provide a guide to the dynamics of this family of maps in the non-invertible case where the two pieces fold onto the same half-plane. We identify parameter regimes for the occurrence of key bifurcation structures, such as period-incrementing, period-adding, and robust chaos. We then apply the results to a classic model of a boost converter for adjusting the voltage of direct current. It is known that for one combination of circuit parameters the model exhibits a border-collision bifurcation that mimics supercritical period-doubling and is non-invertible due to the switching mechanism of the converter. We find that over a wide range of parameter values, even though the dynamics created in border-collision bifurcations is in general extremely diverse, the bifurcation in the boost converter can only mimic period-doubling, although it can be subcritical.

1 Introduction

Periodic and non-periodic oscillations in systems of ordinary differential equations are usually analysed by constructing a return map. In classical settings, where the differential equations
induce a unique smooth flow, such maps are typically smooth and invertible, at least locally [1]. However, for piecewise-smooth differential equations and hybrid systems, return maps are commonly piecewise-smooth [2].

The phase space of a piecewise-smooth map is characterised by the presence of one or more switching manifolds where the map is nonsmooth. This nonsmoothness causes the dynamics to change in a fundamental way at border-collision bifurcations where a fixed point collides with a switching manifold as parameters are varied. Under quite general conditions, these dynamics are captured by a piecewise-linear family known as the border-collision normal form [3, 4, 5]. In two dimensions this family can be written as

\[
\begin{bmatrix} x \\ y \end{bmatrix} \mapsto \begin{cases} 
\tau_L x + y + \mu & , \quad x \leq 0, \\
-\delta_L x & , \\
\tau_R x + y + \mu & , \quad x \geq 0, \\
-\delta_R x & 
\end{cases}
\]

(1)

where the line \( x = 0 \) is the switching manifold, the parameter \( \mu \in \mathbb{R} \) controls the border-collision bifurcation, and \( \tau_L, \delta_L, \tau_R, \delta_R \in \mathbb{R} \) are additional parameters.

The normal form (1) is well-studied as it arises in diverse applications, and, as an extension of the Lozi map [6], serves as a minimal model for chaotic and highly nonlinear dynamics. The dynamics of (1) is remarkably rich — it exhibits chaos robustly [7, 8], can have any number of coexisting attractors [9], of which all could be chaotic [10, 11]. Most studies of (1) have focussed on parameter regimes where (1) is invertible, i.e. \( \delta_L \delta_R > 0 \). For the invertible, dissipative case, a review is provided by [12]; other works that characterise parameter space in some detail include [13, 14, 15, 16].

However, it is perhaps under-appreciated that return maps of piecewise-smooth dynamical systems are often, not only piecewise-smooth, but also non-invertible. This is because a switch to a different mode of operation can readily cause the flow to fold back onto itself, as illustrated below for power converters. Some analysis of (1) has been done in the non-invertible case. For example period-adding is illustrated numerically in [16], global bifurcations of a chaotic attractor in an equivalent map are described in [17], and two-dimensional attractors are identified in [18]. In this paper we provide an overview of the dynamics of (1) when it is non-invertible, specifically with \( \delta_L \delta_R < 0 \). For the special case \( \delta_L \delta_R = 0 \), where the long-term dynamics are essentially one-dimensional, refer to [19, 20].

We begin in §2 by showing how the piecewise-linear normal form (1) applies to border-collision bifurcations of arbitrary, two-dimensional, piecewise-smooth maps. We then study (1) subject to \( \delta_R < 0 < \delta_L \), the specific signs being chosen without loss of generality. The dynamical complexity of (1) means we cannot hope to characterise all dynamics, and for this reason our approach is to chart the essential features. With \( \mu < 0 \) the dominate bifurcation structures are period-adding and robust chaos, §3 while with \( \mu > 0 \) the map exhibits period-incrementing and robust chaos, §4.

In §5 we illustrate the results with the power converter model of Deane [21]. This model exhibits a border-collision bifurcation, and by determining the part of the parameter space of the normal form that this bifurcation corresponds to, we can use our results to characterise the bifurcation. Although in general the dynamics created in border-collision bifurcations is
extremely diverse, it appears this bifurcation acts exclusively as a piecewise-smooth version of period-doubling. Finally §6 provides concluding remarks.

2 Border-collision bifurcations and the normal form

A border-collision bifurcation occurs when a fixed point of a piecewise-smooth map collides with a switching manifold. Here we consider a two-dimensional map with variables \( u, v \in \mathbb{R} \) and parameter \( \eta \in \mathbb{R} \). We assume a border-collision bifurcation occurs at the origin \((u, v) = (0, 0)\) when \( \eta = 0 \), and we wish to understand the dynamics in a neighbourhood of \((u, v; \eta) = (0, 0; 0)\).

We assume the switching manifold is smooth, at least locally, so there exists a smooth coordinate change that shifts the switching manifold to the line \( u = 0 \) \[22\]. Then, assuming the map is continuous and piecewise-\( C^2 \), locally it has the form

\[
\begin{bmatrix}
u \\
v
\end{bmatrix} \mapsto \begin{cases} 
\begin{bmatrix}
 a_{11}^{L}u + a_{11}^{12}v + b_{1}^{1}\
a_{11}^{L}u + a_{11}^{22}v + b_{2}^{1}
\end{bmatrix} + O((|u| + |v| + |\eta|)^2), & u \leq 0, \\
\begin{bmatrix}
a_{11}^{R}u + a_{11}^{12}v + b_{1}^{2}\
a_{11}^{R}u + a_{11}^{22}v + b_{2}^{2}
\end{bmatrix} + O((|u| + |v| + |\eta|)^2), & u \geq 0,
\end{cases}
\]

for some \( a_{11}^{L}, a_{21}^{L}, a_{11}^{R}, a_{21}^{R}, a_{12}, a_{22}, b_{1}, b_{2} \in \mathbb{R} \). Note that the \( v \) and \( \eta \) coefficients of the two pieces of (2) are the same. This is a consequence of the assumed continuity of (2) on \( u = 0 \).

Next we work to bring (2) into the normal form (1).

2.1 A derivation of the normal form

By construction the origin is a fixed point of (2) when \( \eta = 0 \). We now consider fixed points of (2) for small \( \eta \in \mathbb{R} \). Let \( c = (1 - a_{22})b_{1} + a_{12}b_{2} \).

Then the left \((u \leq 0)\) piece of (2) has the fixed point

\[
\begin{bmatrix}
u^{L}(\eta) \\
v^{L}(\eta)
\end{bmatrix} = \frac{1}{(1 - a_{11}^{L})(1 - a_{22}) - a_{12}a_{21}^{R}} \begin{bmatrix}
 a_{21}^{R}b_{1} + (1 - a_{11}^{R})b_{2}
\end{bmatrix} \eta + O(\eta^2),
\]

assuming the denominator in (4) is non-zero. Similarly the right \((u \geq 0)\) piece of (2) has the fixed point

\[
\begin{bmatrix}
u^{R}(\eta) \\
v^{R}(\eta)
\end{bmatrix} = \frac{1}{(1 - a_{11}^{R})(1 - a_{22}) - a_{12}a_{21}^{R}} \begin{bmatrix}
 a_{21}^{R}b_{1} + (1 - a_{11}^{R})b_{2}
\end{bmatrix} \eta + O(\eta^2),
\]

assuming its denominator is non-zero. In a sufficiently small neighbourhood of \((u, v; \eta) = (0, 0; 0)\), these are the only fixed points of (2).

Notice we require \( c \neq 0 \) for the fixed points to move away from the switching manifold at a rate that is asymptotically proportional to \( \eta \). Thus \( c \neq 0 \) is the transversality condition \[23, 24\] that ensures \( \eta \) unfolds the border-collapse bifurcation in a generic fashion.
In view of the switching condition in (2), \((u^L, v^L)\) is a fixed point of (2) only if \(u^L \leq 0\), in which case we say it is admissible. Similarly \((u^R, v^R)\) is an admissible fixed point of (2) if \(u^R \geq 0\). If \(u^L < 0\), the stability of \((u^L, v^L)\) is governed by the eigenvalues of the Jacobian matrix of (2) evaluated at \((u^L, v^L)\). This matrix is
\[
\begin{bmatrix}
a_{11}^L & a_{12}^L \\
 a_{21}^L & a_{22}^L
\end{bmatrix} + O(\eta).
\] To leading order its trace and determinant are
\[
\tau_L = a_{11}^L + a_{22}^L, \quad \delta_L = a_{11}^L a_{22}^L - a_{12}^L a_{21}^L. \tag{6}
\]
We similarly define
\[
\tau_R = a_{11}^R + a_{22}^R, \quad \delta_R = a_{11}^R a_{22}^R - a_{12}^R a_{21}^R, \tag{7}
\]
for the right piece of (2). By removing the nonlinear terms from each piece of (2) and applying the coordinate change
\[
x = u, \tag{8}
\]
\[
y = -a_{22}^L u + a_{12}^L v + (a_{22}^L b_1 - a_{12}^L b_2)\eta, \tag{9}
\]
\[
\mu = c\eta, \tag{10}
\]
we arrive at the normal form (1) with \(\tau_L, \delta_L, \tau_R, \) and \(\delta_R\) given by (6) and (7). This coordinate change is invertible when \(c \neq 0\) (discussed above) and \(a_{12} \neq 0\) (otherwise (2) decouples into two one-dimensional maps).

2.2 The utility of the normal form

The dynamics of the normal form (1) approximates the dynamics of (2) for small values of \(u, v,\) and \(\eta\). Presently there is little mathematical theory clarifying the validity of this approximation, but in practice the normal form is useful for characterising the dynamics created in border-collision bifurcations. For example, if the normal form exhibits a hyperbolic periodic solution, this solution also exists for (2) \[5\]. This type of persistence result has recently been extended to chaotic attractors \[25\].

Since the normal form is piecewise-linear, the structure of its dynamics is independent of the magnitude of \(\mu\). If \(\mu < 0\) its value can be scaled to \(-1\), while if \(\mu > 0\) its value can be scaled to \(1\). We therefore study the normal form with \(\mu = -1\) to understand the dynamics on one side of the border-collision bifurcation, and with \(\mu = 1\) to understand the dynamics on the other side of the border-collision bifurcation.

With \(\mu = 0\) the origin is a fixed point of the normal form. If it is asymptotically stable then (2) has a local attractor on each side of the border-collision bifurcation \[26\]. However, the normal form is non-differentiable at the origin, so its stability can be difficult to ascertain \[27\] \[28\]. For instance in the non-invertible case the origin can be asymptotically stable even when both pieces of the map are area-expanding \[29\].

If \(\delta_L, \delta_R < 0\), then, in view of the substitution \((x, y, \mu) \leftrightarrow (-x, -y, -\mu)\) that leaves the normal form invariant other than switching ‘left’ and ‘right’, we can assume \(\delta_L > 0\) and \(\delta_R < 0\). With \(\delta_L > 0\) and \(\delta_R < 0\) the normal form maps both left and right half-planes to the upper half-plane \((y \geq 0)\).
Figure 1: The lower plot is a bifurcation diagram of the normal form (1) with (11). As the value of $\mu$ is increased through 0, a stable period-3 solution changes to a stable period-4 solution. The upper plots are phase portraits with $\mu = \pm 1$ (red circle: unstable fixed point; red triangles: unstable period-2 solution; blue circles: stable period-3 and period-4 solutions; green line: switching manifold).

2.3 An example of the dynamics of the normal form

Fig. 1 shows a bifurcation diagram and phase portraits of the normal form (1) with

$$(\tau_L, \delta_L, \tau_R, \delta_R) = (-1, 2, -1, -0.2).$$

Here $\delta_L > 0$ and $\delta_R < 0$ so all invariant sets lie in the upper half-plane ($y \geq 0$). For this example the border-collision bifurcation brings about a transition from a stable period-3 solution to a stable period-4 solution. As with all bounded invariant sets of the normal form, these solutions contract linearly to the origin as $\mu \to 0$, and this is evident in the bifurcation diagram. The period-3 solution for $\mu < 0$ consists of one point in the left half-plane and two points in the right half-plane. Its symbolic representation is therefore $LRR$ (or any cyclic permutation of this) and we refer to it as an $LRR$-cycle. Similarly the period-4 solution for $\mu > 0$ is an $LRRR$-cycle. Based on symbolic representations, we can characterise the existence, admissibility, and stability of periodic solutions in a general manner [5, 30].
3 The dynamics for $\mu < 0$

Our aim here is to obtain a broad understanding of the attractors of (1) with $\mu < 0$ and $\delta_L > 0$, $\delta_R < 0$, $\tau_L \in \mathbb{R}$, and $\tau_R \in \mathbb{R}$. As explained above, by scaling it is sufficient to consider $\mu = -1$. We have found it helpful to study two-dimensional slices of parameter space defined by fixing the values of $\delta_L$ and $\delta_R$, and study how the dynamics on these slices differs for different values of $\delta_L$ and $\delta_R$. This is summarised by Fig. 2. In the top left this figure shows the open fourth quadrant

$$Q_4 = \{(\delta_L, \delta_R) | \delta_L > 0, \delta_R < 0\},$$

and has four curves that divide $Q_4$ into seven subsets where $(\tau_L, \tau_R)$-two-parameter bifurcation diagrams have similar features. This division is based on the existence of period-$n$ periodicity regions for $n = 1, 2, 3$. Certainly one could divide $Q_4$ further by considering more features in the bifurcation diagrams, but it is not clear that this would be helpful [31].

![Fig. 2: Seven representative two-parameter bifurcation diagrams of the normal form (1) with $\mu = -1$ obtained by fixing $\delta_L$ and $\delta_R$ and varying $\tau_L$ and $\tau_R$ (black: chaotic, quasi-periodic, or high period attractor; white: no attractor; red: stable fixed point; cyan: stable period-2 solution; yellow: stable period-3 solution; other colours: periods 4–30 as indicated in the colour bar). The figure also shows how the fourth quadrant of the $(\delta_L, \delta_R)$-plane can be divided into subsets where the bifurcation diagrams have similar features.](image-url)
3.1 Numerical methods

Before we describe the seven bifurcation diagrams in Fig. 2 in more detail, we first explain how they were computed. For each point in a 1000 × 1000 equispaced grid of \((\tau_L, \tau_R)\) values, we computed \(N = 10^4\) iterates \((x_i, y_i)\) of the forward orbit of a random initial point \((x_0, y_0)\). If the norm of \((x_i, y_i)\) exceeded \(10^6\) for any \(i\) we concluded the orbit diverges and coloured this parameter point white. Otherwise we looked to see if the orbit converges to a periodic solution. If we could find a smallest \(1 \leq p \leq 30\) for which the norm of \((x_N, y_N) - (x_{N-p}, y_{N-p})\) was less than a tolerance of \(10^{-6}\), we concluded the orbit converges to a period-\(p\) solution and coloured the point according to the colour bar. If no such period was detected the point was coloured black. In this case the orbit most likely converges to either a periodic solution with period greater than 30, a quasi-periodic attractor, or a chaotic attractor. Additional techniques were used to compute the period-3 regions in (i) and (vii). Following [5] for these we solved for the \(LRR\)-cycle exactly and checked admissibility and stability explicitly.

By using random initial points the bifurcation diagrams reveal areas where multiple attractors coexist and areas where attractors are not globally stable. For example the bottom three bifurcation diagrams are speckled white because the attractors are not globally attracting so some initial points give forward orbits that diverge.

3.2 Seven different two-parameter bifurcation diagrams

First consider \((\delta_L, \delta_R)\) in subset (i). In this case any \((\tau_L, \tau_R)\)-bifurcation diagram has a vertical red strip, \(-\delta_L - 1 < \tau_L < \delta_L + 1\), where the left half-map has a stable fixed point. As we cross the \(\tau_L = -\delta_L - 1\) boundary of this strip, from right to left, this fixed point attains an eigenvalue of \(-1\) and becomes unstable. This is not a period-doubling bifurcation as the normal form does not have the required nonlinearity, nevertheless a stable period-2 solution \((LR\text{-cycle})\) exists in a certain region (coloured cyan). This region is bounded below by the curve \(\tau_R = \frac{(1+\delta_L)(1+\delta_R)}{\tau_L}\), where the \(LR\)-cycle has an eigenvalue of \(-1\), and bounded above by \(\tau_R = \frac{(\delta_L-1)(1-\delta_R)}{\tau_L}\), where it has an eigenvalue of 1. Fig. 2(i) also has regions where there exists a stable \(LRR\)-cycle (yellow) and a stable \(LRRR\)-cycle (brown). For different values of \((\delta_L, \delta_R)\) in subset (i), our numerical explorations have found that other periodicity regions can exist, particularly if \(|\delta_R|\) is small, but the corresponding symbolic itinerary always contains exactly one \(L\).

To move from subset (i) to (ii) we cross the line \(\delta_L = 1\) at which the vertical red strip vanishes. On the line \(\delta_L = 1\), and with \(-2 < \tau_L < 2\), the left half-map has purely imaginary eigenvalues. For generic families of smooth maps this signals the occurrence of a Neimark-Sacker bifurcation at which an invariant circle is created. From a curve of Neimark-Sacker bifurcations there emanate Arnold tongues where the dynamics on the invariant circle includes a stable periodic solution (i.e. is mode-locked) [24, 32]. In our piecewise-linear setting, similar features arise [13]. An invariant circle is often created, as in Fig. 3(a). However, since the map is non-invertible the interior of the circle does not map to itself.

Fig. 2(ii) shows a typical bifurcation diagram for subset (ii). Stable periodic solutions exist in the coloured regions (Arnold tongues) which overlap in places resulting in coexisting attractors, Fig. 3(b) shows an example. Overall the Arnold tongues have a period-adding...
structure as discussed below.

![Figure 3](image-url)

**Figure 3:** Panel (a) is a phase portrait of (1) with \( \mu = -1 \) and \((\tau_L, \delta_L, \tau_R, \delta_R) = (-1.2, 0.6, -0.2)\) showing an attracting invariant circle. Panel (b) is with instead \((\tau_L, \delta_L, \tau_R, \delta_R) = (-3.126, 2, -0.3785, -0.1)\) where the map has a stable LR-cycle (blue triangles) and a stable LRR-cycle (blue circles). The boundary between the basins of attraction of these solutions is the stable manifold of a saddle-type LLR-cycle (red circles).

To move from subset (ii) to (iii) we cross the curve \( \delta_L = -1, \) labelled \( \gamma_2, \) which is where the cyan region vanishes. This can be explained as follows. The eigenvalues that govern the stability of an admissible LR-cycle are those of the matrix \( A_R A_L \). The curve \( \gamma_2 \) is where the determinant of this matrix is \(-1\). Below \( \gamma_2 \) we have \( \det(A_R A_L) < -1 \) so the LR-cycle cannot be stable for any values of \( \tau_L \) and \( \tau_R \).

By next crossing the curve \( \delta_L = 1, \) labelled \( \gamma_3, \) the yellow region (for the existence of a stable LRR-cycle) vanishes for a similar reason. One could further identify additional curves for higher periods but this is complicated by the fact that for higher periods multiple symbolic representations occur.

Our numerical explorations suggest that throughout subset (iv) the only attractors that are possible are chaotic. But unlike when the normal form is invertible — where chaotic attractors are typically quasi-one-dimensional, formed from one or more one-dimensional unstable manifolds [8] — in the non-invertible setting attractors can be two-dimensional, Fig. 4(a). Glendinning [18] proved that throughout an open subset of parameter space the normal form has a two-dimensional attractor for one sign of \( \mu \) and a stable fixed point for the other sign of \( \mu \). This shows that the sudden and local transition of a stable fixed point to a two-dimensional attractor can occur via a border-collision bifurcation in a generic (codimension-one) fashion. Coexisting chaotic attractors are also possible, Fig. 4(b). In fact for all \( n \geq 1 \) there exist parameter combinations for which the normal form has \( n \) coexisting chaotic attractors [11].

Next as we move in \( Q_4 \) from (iv) into (v), then into (vi), and lastly into (vii), we again cross the curves \( \delta_L = 1, \gamma_2, \) and \( \gamma_3, \) in this order. Consequently the vertical red strip reappears
(fixed point), then the cyan region reappears (LR-cycle), and lastly a yellow region reappears (LRR-cycle). The difference between subsets (i) and (vii) is that the yellow region has two connected components in subset (i), but only one connected component in subset (vii). The boundary between these subsets is a curve $\zeta_3$ derived in Appendix A.

### 3.3 Period-adding

Arnold tongues are shown in Fig. 2(ii) and more closely in the magnification, Fig. 5(a). While the precise location and shape of the Arnold tongues depends on the values of $\delta_L$ and $\delta_R$, they have a broadly consistent two-dimensional structure. This structure is described in [16] for our non-invertible setting, in [20] for the special case $\delta_L\delta_R = 0$, and in several papers [33, 34, 35, 36] (each motivated by a different physical application) for the invertible case.

In the Arnold tongues only certain ‘rotational’ symbolic itineraries are possible [37]. As in the classical smooth setting [38, 39], the periodic solution can be assigned a rotation number $\frac{m}{p} \in (0, 1)$, where $p$ is the period and $m$ represents the number of rotations per period. As we move left to right across Fig. 5(a), the rotation number decreases roughly monotonically.

Between any two Arnold tongues of frequencies $\frac{m_1}{p_1}$ and $\frac{m_2}{p_2}$ with $m_1p_2 - m_2p_1 = \pm 1$, there are usually more Arnold tongues, the largest of which has frequency $\frac{m_1 + m_2}{p_1 + p_2}$. Such Farey addition [40, 41] repeats indefinitely and, as in the smooth setting, explains the ordering and relative size of the Arnold tongues. One-parameter slices that cut horizontally through Fig. 5(a) consequently display periodic windows where the period of a window is often given by adding the periods of the largest windows on either side. Fig. 5(b) shows a typical example where we can see period-5 and period-6 windows, and between them a period-11 window (centred at about $\tau_L = 1.2$). This structure is referred to as period-adding [2].
Figure 5: Panel (a) is a magnification of the two-dimensional bifurcation diagram, Fig. 2(ii), showing Arnold tongues (regions where periodic solutions are stable) up to period 30. Panel (b) is a one-parameter bifurcation diagram obtained by further fixing $\tau_R = 0.2$.

However, unlike in the smooth setting, the Arnold tongues also exhibit structure in a second direction. As we move up Fig. 5(a) the fraction of $L$’s in the symbolic itineraries decreases. As we cross any shrinking point, where an Arnold tongue has zero width, one $L$ in the symbolic itinerary associated with the stable periodic solution changes to an $R$.

4 An overview of the dynamics with $\mu > 0$

We now consider $\mu > 0$. As discussed in §2 it suffices to consider $\mu = 1$.

The dynamics are summarised by Fig. 6 which shows four representative $(\tau_L, \tau_R)$-two-parameter bifurcation diagrams and shows how $Q_4$, for the pairs $(\delta_L, \delta_R)$, can be divided into different subsets based on features of the bifurcation diagrams. If $-1 < \delta_R < 0$ the bifurcation diagram has a (red) horizontal strip $-\delta_R - 1 < \tau_R < \delta_R + 1$ where the right half-map has a stable fixed point. Otherwise the dominate periodic solutions are those whose symbolic itinerary contains exactly one $R$. That is, for a period-$p$ solution the itinerary is $L^{p-1}R$ (or a cyclic permutation of this). Its stability multipliers are the eigenvalues of $M_p = A_R A_{L}^{p-1}$. Notice $\det(M_p) = \delta_L^{-1} \delta_R < 0$ (because $\delta_R < 0 < \delta_L$). So if $\det(M_p) > -1$ then the $L^{p-1}R$-cycle is stable when

$$-\det(M_p) - 1 < \text{trace}(M_p) < \det(M_p) + 1. \tag{13}$$

Regions where $L^{p-1}R$-cycles are stable and admissible are coloured in Fig. 6. Roughly speaking these regions are narrow and aligned vertically. Their left boundary is where $\text{trace}(M_p) = \det(M_p) + 1$, where $M_p$ has an eigenvalue 1, and their right boundary is where $\text{trace}(M_p) = -\det(M_p) - 1$, where $M_p$ has an eigenvalue $-1$. Upper boundaries are where admissibility is lost via a border-collision bifurcation where one point of the $L^{p-1}R$-cycle is located on the switching manifold.
Figure 6: Four representative two-parameter bifurcation diagrams of (1) with $\mu = 1$ using the same colour scheme as Fig. 2. The left plot shows curve $\gamma_p$ that form a boundary for the existence of a region in the bifurcation diagrams where the map has a stable $L^{p-1}R$-cycle.
As the pair \((\delta_L, \delta_R)\) is varied, the left and right boundaries coincide, and the stability region vanishes, when \(\text{det}(M_p) = -1\). That is,

\[
\delta_R = \frac{-1}{\delta_L^{p-1}}.
\]

(14)

These are curves labelled \(\gamma_p\) in Fig. 6. As \(p \to \infty\) the curves converge to \(\delta_L = 1\) and part of the \(\delta_L\)-axis.

Thus with \(0 < \delta_L < 1\) and \(-1 < \delta_R < 0\), for each \(p \geq 2\) the \((\tau_L, \tau_R)\)-bifurcation diagram has a region where there exists a stable \(L^{p-1}R\)-cycle. The top-left bifurcation diagram of Fig. 6 provides a typical example. Only finitely many regions are visible because as \(p\) increases they only exist for successively larger (more negative) values of \(\tau_R\). By then increasing the value of \(\delta_L\), but keeping \(\delta_R\) fixed, the regions vanish as we cross the curves \(\gamma_p\) for successively decreasing values of \(p\). The top-right bifurcation diagram of Fig. 6 is for \((\delta_L, \delta_R)\) between \(\gamma_3\) and \(\gamma_4\), so the period-\(p\) regions exist for \(p = 2\) and \(p = 3\) but no higher values of \(p\).

If instead we fix \(\delta_R < -1\) and start with \(\delta_L\) such that \((\delta_L, \delta_R)\) lies to the left of \(\gamma_2\), then again the period-\(p\) region exists for all \(p \geq 2\) (bottom-left bifurcation diagram). But now as we increase the values of \(\delta_L\) the regions vanish for successively increasing values of \(p\). With \(\delta_L > 1\) and \(\delta_R < -1\), as in the bottom-right bifurcation diagram, stable, admissible periodic solutions cannot exist and all attractors appear to be chaotic. Here the region where an attractor exists has a similar spiked shape to the region of [29] where the origin is asymptotically stable when \(\mu = 0\). This is because asymptotic stability of the origin with \(\mu = 0\) implies the existence of a local attractor for all \(\mu \neq 0\) [26].

In the bifurcation diagrams, just past the right boundary of a period-\(p\) region where the \(L^{p-1}R\)-cycle attains an eigenvalue of \(-1\), there can exist a region where a period-\(2p\) solution is stable. For example in the brown region of the top-right bifurcation diagram of Fig. 6, there exists a stable \(LRRR\)-cycle.

In the black regions of the bifurcation diagrams the attractor is typically chaotic. Attractors can coexist and Fig. 7(a) shows a typical example. Here the boundary between two basins of attraction is given by the stable manifold of a saddle \(LRR\)-cycle.

Chaotic attractors undergo several global bifurcations as we move about the black regions. These are described in [17] for a one-parameter family. Fig. 7(b) shows an example of an attractor in their family (in terms of the normal for [11]). They found the attractor can be bounded by images of the switching manifold and sometimes also by one or more unstable manifolds. Bifurcations occur as the geometry of these one-dimensional objects changes.

5 Application to power converters

Whenever an electrical device requires the use of current with a voltage different to that of its power supply, it is necessary to alter the voltage level. This is usually achieved with a power converter. Power converters commonly employ rapid switching to minimize energy loss and allow components (such as inductors and capacitors) to be small in size.

Here we consider the boost converter model of Deane [21]. This model has two variables: \(u(t)\) and \(v(t)\) for the current and voltage, respectively, in an inductor. To regulate the output
Figure 7: Panel (a) is a phase portrait of (1) with $(\tau_L, \delta_L, \tau_R, \delta_R) = (0.5, 0.5, -2, -0.5)$. There exists a stable LLR-cycle (blue circles) and an apparently chaotic attractor (also blue). The stable manifold of a saddle LRR-cycle forms the boundary between their basins of attraction. Panel (b) is a phase portrait of (1) with $(\tau_L, \delta_L, \tau_R, \delta_R) = (2, 0.75, -1, -1.25)$ corresponding to Fig. 11 of [17].

Voltage the converter has a switch that closes whenever $\frac{t}{T} \in \mathbb{Z}$, where $t \in \mathbb{R}$ is time and $T > 0$ is the period of the converter. While the switch is closed the variables evolve according to

$$\dot{u} = \frac{V_I}{L}, \quad \dot{v} = -\frac{1}{RC} v,$$

and Deane [21] gives the following parameter values

$$R = 20, \quad L = 0.001, \quad C = 0.000012, \quad T = 0.0001, \quad V_I = 10. \quad (16)$$

The switch opens whenever the value of the current $u(t)$ reaches a threshold value $I_{\text{ref}}$, and while the switch is open the variables evolve according to

$$\dot{u} = \frac{V_I}{L} - \frac{1}{L} v, \quad \dot{v} = \frac{1}{C} u - \frac{1}{RC} v.$$  \quad (17)

Fig. 8 shows a typical time series. Notice the system evolves according to (15) (switch closed) until $u(t) = I_{\text{ref}}$, then evolves according to (17) until $t = nT$ for some $n \in \mathbb{Z}$. For the given parameter values the dynamics of the converter converges to a period-2T orbit.

Fig. 9 shows a bifurcation diagram obtained by varying the value of $I_{\text{ref}}$. For small values of $I_{\text{ref}}$ solutions converge to a period-T orbit. This solution loses stability in a period-doubling bifurcation at $I_{\text{ref}} \approx 1.7060$ (labelled PD in Fig. 9) past which solutions converge to a period-2T orbit. The period doubles again at $I_{\text{ref}} \approx 2.3721$, except this is not another period-doubling bifurcation, it is a border-collision bifurcation (labelled BCB) that mimics supercritical period-doubling. In the remainder of this section we analyse this bifurcation by
Figure 8: A time series of the boost converter model with (16) and $I_{\text{ref}} = 2$. A switch in the converter closes whenever $\frac{t}{T} \in \mathbb{Z}$ (vertical grey lines) after which the current $u(t)$ increases. The switch opens whenever $u(t) = I_{\text{ref}}$ after which the current decreases.

Figure 9: A numerically computed bifurcation diagram of the boost converter model with (16) (PD: period-doubling bifurcation; BCB: border-collision bifurcation).
using the results of the previous sections and explain how it can differ for different values of the parameters \(16\).

To analyse the border-collision bifurcation, as in [21] we construct a stroboscopic map. Given values \(u\) and \(v\) for the variables at a time \(t = nT\), where \(n \in \mathbb{Z}\), let \((u', v') = g(u, v)\) be the values of variables at \(t = (n+1)T\). The map \(g\) is piecewise-smooth, specifically it has the form

\[
g(u, v) = \begin{cases} 
g_L(u, v), & u \leq I_{\text{ref}} - \frac{V_T}{L}, \\
g_R(u, v), & u \geq I_{\text{ref}} - \frac{V_T}{L},
\end{cases}
\]

because the switch may or not open between the times \(nT\) and \((n+1)T\). If \(u < I_{\text{ref}} - \frac{V_T}{L}\) the switch is closed for the whole period and from the flow of (15) we obtain

\[
g_L(u, v) = \left[ u + \frac{V_T}{L} \right] e^{-\frac{t}{RC} v}.
\]

If \(u > I_{\text{ref}} - \frac{V_T}{L}\) the switch opens at \(t = nT + t_{sw}\) where \(t_{sw} = \frac{L}{V_T} (I_{\text{ref}} - u)\). At this time the current and voltage are given by (19) except with \(t_{sw}\) in place of \(T\). By then evolving these values under the flow of (17) (readily obtainable because (17) is affine) we obtain (after much simplification)

\[
g_R(u, v) = e^{-kt} \left[ \left( I_{\text{ref}} - \frac{V_T}{R} \right) \cos(\omega t) + \frac{1}{\omega L} \left( V_I - e^{-2kt_{sw}v} + kL\left( I_{\text{ref}} - \frac{V_T}{R} \right) \sin(\omega t) \right) \sin(\omega t) + \left( V_I - e^{-2kt_{sw}v} \right) \left( \frac{k}{\omega} \sin(\omega t) - \cos(\omega t) \right) \right] + \left[ \frac{V_T}{R} \right] V_L,
\]

where \(k = \frac{1}{2RC}, \omega = \sqrt{\frac{1}{LC} - k^2}\), and \(t = T - t_{sw}\). These formulas are also given in [21].

The period-2\(T\) orbit described above corresponds to a period-two solution (RR-cycle) of \(g\). The border-collision bifurcation occurs when one point of this solution collides with the switching manifold of \(g\). Thus in a neighbourhood of this point the second iterate of \(g\), call it \(f\), has the form

\[
f(u, v) = \begin{cases} 
(\underbrace{g_R \circ g_L}_{f^1}(u, v)), & u \leq I_{\text{ref}} - \frac{V_T}{L}, \\
(\underbrace{g_R \circ g_R}_{f^2}(u, v)), & u \geq I_{\text{ref}} - \frac{V_T}{L}.
\end{cases}
\]

We can then bring (21) into the general form (2) via a change of variables. To end up with \(\delta_R < 0 < \delta_L\) (matching Sections 3 and 4) we assume this change of variables is done so that \(g_R \circ g_R\) becomes the left piece of (2) and \(g_R \circ g_L\) becomes the right piece of (2).

Since we have explicit formulas for \(g_L\) and \(g_R\), it is a straight-forward (although tedious) exercise to evaluate the Jacobian matrices \(D(g_R \circ g_R)\) and \(D(g_R \circ g_L)\) at the border-collision bifurcation. Numerically we find that with the parameter values \(16\), at the border-collision bifurcation the trace and determinant of \(D(g_R \circ g_R)\) are

\[
\tau_L = -0.2726, \quad \delta_L = 0.1136,
\]

and the trace and determinant of \(D(g_R \circ g_L)\) are

\[
\tau_L = -1.4992, \quad \delta_L = -0.2222,
\]
to four decimal places. With these values the border-collision normal form has a stable fixed point for \( \mu < 0 \) and a stable \( LR \)-cycle for \( \mu > 0 \). Specifically for \( \mu < 0 \), \((\delta_L, \delta_R)\) belongs to subset (vii) of Fig. 2 and \((\tau_L, \tau_R)\) belongs to the red strip \(-\delta_L - 1 < \tau_L < \delta_L + 1\) where the left half-map has a stable fixed point. For \( \mu > 0 \), \((\delta_L, \delta_R)\) belongs to the top-left part of \( Q_4 \) and \((\tau_L, \tau_R)\) belongs to the cyan region where there exists a stable \( LR \)-cycle. In terms of the stroboscopic map \( g \), this corresponds to a stable period-two solution bifurcating to a stable period-four solution as the value of \( I_{\text{ref}} \) is increased to pass through the border-collision bifurcation, which confirms what we are seeing in Fig. 9.

We now consider parameter values different to (16). As we decrease the value of the resistance \( R \) from the value 20 and keep the other values in (16) fixed, a border-collision bifurcation still occurs but at a varying value of \( I_{\text{ref}} \), as shown in Fig. 10. The values of \( \tau_L \), \( \delta_L \), \( \tau_R \), and \( \delta_R \) also vary with \( R \), as shown in Fig. 11. These values belong to the same subsets and regions of Figs. 2 and 6 until at \( R \approx 16.8623 \) we exit the cyan region for \( \mu > 0 \). Specifically we cross the left boundary \( \tau_R = \frac{(1+\delta_L)(1+\delta_R)}{\tau_L} \) where the \( LR \)-cycle attains an eigenvalue of 1. Beyond this boundary the border-collision normal form has no local attractor for \( \mu > 0 \), and an unstable \( LR \)-cycle is created for \( \mu < 0 \).

In terms of \( g \), the border-collision bifurcation now mimics subcritical period-doubling because an unstable period-four solution is created and grows as the value of \( I_{\text{ref}} \) decreases. However this solution soon becomes stable in a saddle-node bifurcation. In the two-parameter bifurcation diagram, Fig. 10, the curve of saddle-node bifurcations emanates from the curve of border-collision bifurcations with a quadratic tangency at the codimension-two point \((R \approx 16.8623)\) in accordance with the bifurcation theory for such points [42, 43].

![Figure 10: A two-parameter bifurcation diagram of the boost converter model obtained by varying \( I_{\text{ref}} \) and \( R \) and keeping all other parameter values fixed as in (16) (SN: saddle-node bifurcation; BCB: border-collision bifurcation).](image)

Thus the power converter has a small region of bistability (between the saddle-node and border-collision bifurcations) where stable period-2\( T \) and period-4\( T \) orbits coexist. Below the codimension-two point and to the right of the border-collision bifurcation, the power converter model has a stable period-4\( T \) orbit whereas the corresponding border-collision normal form
has no attractor because here the period-4T orbit is a consequence of nonlinearities in \( g \) that are not captured by the normal form.

![Figure 11: The values of \( \tau_L, \delta_L, \tau_R, \) and \( \delta_R \) at the border-collision bifurcation of the boost converter. The parameter values are given by (16) except \( R \) is variable. The value of \( I_{\text{ref}} \) is that at which the border-collision bifurcation occurs, see Fig. 10. We have also plotted the quantity \( \tau_R - \frac{1 + \delta_L (1 + \delta_R)}{\tau_L} \). The sign of this quantity governs the criticality of the border-collision bifurcation (in the context of the period-4T orbit).](image)

We explored the effect of varying the other model parameters from their values in (16) and found that the corresponding values of \( \tau_L, \delta_L, \tau_R, \) and \( \delta_R \) either remained within the subsets and regions of Figs. 2 and 6 described above, or exited the cyan region by crossing its left boundary. This suggests that over a wide range of parameter values, the border-collision bifurcation of the power converter only mimics period-doubling, but the doubling can be supercritical or subcritical depending on the parameters.

6 Discussion

Border-collision bifurcations occur in mathematical models of diverse physical phenomena. Subject to reasonable genericity conditions, in two dimensions the leading-order dynamics are characterised by four scalar parameters, \( \tau_L, \delta_L, \tau_R, \) and \( \delta_R \), see §2. In this paper we have attempted to provide a high-level overview of the dynamics of normal form in the non-invertible case, \( \delta_L \delta_R < 0 \). To grasp four-dimensional parameter space, we have considered two-dimensional slices (two-parameter bifurcation diagrams) defined by fixing the values of \( \delta_L > 0 \) and \( \delta_R < 0 \), and studied how the dynamics across the slices is different with different values. With instead \( \delta_L < 0 \) and \( \delta_R > 0 \) the same dynamical transitions occur when the sign of the border-collision bifurcation parameter \( \mu \) is reversed.
The results are summarised by Figs. 2 and 6. The two figures correspond to different sides of the border-collision bifurcation. The intention is for these to be applied to border-collision bifurcations in models to make predictions about what dynamics are created and how the dynamics differs for different parameter values.

We illustrated this in §5 for a classic boost converter model. The parameter values of 21 correspond a red region (stable fixed point) in Fig. 2 and a cyan region (stable LR-cycle) in Fig. 6. Thus the bifurcation in the converter affects a doubling of the period. As we vary the parameter values of the converter, we move about Figs. 2 and 6. Numerically we found we remained in the red region but could exit the cyan region by passing through a boundary where the LR-cycle loses stability. This has the effect of flipping the criticality of the period-doubling-like bifurcation in the converter.

A Existence of period-3 regions

![Figure 12: A two-parameter bifurcation diagram repeating Fig. 2(i) but over a smaller range of τL and τR values. In the yellow region the map with μ < 0 has a stable LRR-cycle. This region has two boundaries given by (24) and (25).](image)

Here we derive the curve ζ3 that forms the boundary between subsets (i) and (vii) of Fig. 2. For any (δL, δR) in subset (i), the (τL, τR)-bifurcation diagram has two regions where there exists a stable LRR-cycle, Fig. 2(i). The curve ζ3 is where the upper region, shown more clearly in Fig. 12 shrinks to a point.

The upper region has two boundaries. The left boundary is where the LRR-cycle loses stability by attaining an eigenvalue of −1. Its eigenvalues are those of $M = A_LA_R^2$, so an eigenvalue of −1 occurs when $\det(M) + \text{trace}(M) + 1 = 0$. By directly evaluating and rearranging this equation we find that the left boundary is given by

$$\tau_L = \frac{\tau_R(\delta_R + \delta_L) - \delta_R^2\delta_L - 1}{\tau_R^2 - \delta_R}. \quad (24)$$

The right boundary is where the LRR-cycle undergoes a border-collision bifurcation and becomes virtual by having one of its points collide with the switching manifold. By direct
calculations, or by using the methods in [5], it is a simple exercise to show that the bifurcation occurs when \( \det(I + A_R + A_RA_L) = 0 \). By evaluating this equation we obtain the formula

\[
\tau_L = \frac{\delta_L(1 - \delta_R) - \tau_R - 1}{\tau_R + \delta_R},
\]

(25)

for the right boundary of the upper region.

The two vertices of this region (the tips of the ‘horns’ of the crescent) satisfy both (24) and (25). By equating these we can eliminate \( \tau_L \) to obtain

\[
\alpha \tau_R^3 + b \tau_R^2 + c \tau_R + d = 0,
\]

(26)

where

\[
\begin{align*}
\alpha &= 1, \\
b &= \delta_L \delta_R + \delta_R + 1, \\
c &= -\delta_L \delta_R^2 + \delta_L \delta_R + \delta_R^2 - \delta_R - 1, \\
d &= -\delta_L \delta_R^3 - \delta_L \delta_R^2 + \delta_L \delta_R - 2 \delta_R.
\end{align*}
\]

That is, the \( \tau_R \)-values of the vertices satisfy the cubic (26). The region vanishes when the two vertices coincide, thus when the discriminant of (26) is zero. The discriminant of (26) is

\[
\Delta = 18abcd - 4b^3d + b^2c^2 - 4ac^3 - 27a^2d^2,
\]

(27)

therefore the curve \( \zeta_3 \) is given implicitly by the two-variable polynomial equation \( \Delta = 0 \). This curve is shown in Fig. 2. As \( \delta_L \) is varied from 0 to 1, it appears to decrease monotonically from \( \delta_R \approx -0.08238 \) to \( \delta_R = -1 \).
