Abstract—In this paper we investigate the task of detecting carrier frequency differences from demodulated single sideband signals by examining the pitch contours of the received baseband speech signal in the short-time spectral domain. From the detected pitch frequency trajectory and its harmonics a carrier frequency difference, which is caused by demodulating the radio signal with the wrong carrier frequency, can be deduced. A computationally efficient realization in the power cepstral domain is presented. The core component, i.e., the pitch tracking algorithm, is shown to perform comparably to a state of the art algorithm. The full carrier frequency difference estimation system is tested on recordings of real transmissions over HF links. A comparison with an existing approach shows improved estimation accuracy, both on short and longer speech utterances.

Index Terms—Carrier Frequency Difference, SSB, Pitch Tracking

I. INTRODUCTION

The scenario at hand envisions a radio station listening on a fixed, pre-selected frequency, and seeking for single sideband (SSB) modulated high frequency (HF) signals. If the receiver selects a different carrier frequency than the transmitter, the demodulated signal contains a frequency shifted version of the original speech signal originating from the carrier frequency difference [1]. This has a detrimental effect on the intelligibility of the transmitted speech signal [2]. Fig. 1 shows the spectrogram of a demodulated signal from a station operating at a carrier frequency difference of 500 Hz compared to the transmitter.

To improve intelligibility, the carrier frequency difference should be estimated and the signal shifted in frequency to remove the difference. This contribution is concerned with the first task, the determination of the carrier frequency difference from the demodulated speech signal. The second task, the compensation, is rather straightforward and will not be considered here.

A carrier frequency difference can be estimated by investigating the statistical properties of speech, e.g., the modulation symmetry [3] or the spectral envelope [4]. The contribution [3] utilizes a third-order modulation spectral analysis that, however, limits the analyzable spectrum to one-fourth of its total width, and [4] proposes a fundamental harmonic frequency detector that requires relatively long speech segments for reliable estimation in noisy conditions. Training based frequency offset estimation has been proposed in [5], where GMM-SVMs, i-Vectors and deep neural networks are employed. The main disadvantage here is the requirement of having a representative and large enough data set for training, as HF transmissions include a variety of distortions.

In this paper we follow the idea of [1, 4, 5]: By detecting the typical pitch structures in the spectrogram, a possible carrier frequency difference becomes apparent. Fundamental frequency estimation, or pitch tracking, has been a research topic for years with applications in signal enhancement and speaker identification tasks. Various approaches are known from the literature, e.g., RAPT [6], STRAIGHT [7], YIN [8] and YAAP [9]. Since most approaches are based on correlation techniques, be it in the time [8] or frequency domain [7] or even in both domains [9], comparative studies show only small differences between the algorithms in terms of precision [10] as they all depend on similar features. Detecting candidates for periodic signals within the physical range of the vocal cord’s oscillation frequencies is usually the first step, which is followed by a post-processing for candidate refinement and subsequent smoothing [6, 9]. Besides time and frequency domain, also cepstral domain estimators have been proposed [11]. Clearly, all methods suffer from low signal-to-noise ratio (SNR) ratios [10] and robustness to distortions is an important aspect. Here, new approaches based on deep neural networks (DNNs) reported promising results [12].

However, pitch tracking with the purpose of frequency difference estimation poses different constraints compared to the pure pitch tracking task, since in our scenario the pitch and its harmonics are shifted by an arbitrary frequency, requiring

Figure 1: Spectrogram of a signal transmitted over HF and demodulated with 500 Hz carrier frequency difference. Marked in black are the carrier frequency difference (dashed) and the pitch traces including two harmonics.
an open range search for all possible shifts.

The contributions of this paper are two-fold. First, we introduce and discuss our new approach to carrier frequency difference estimation named "Rake". It is based on accumulated log-energy values and enables the classification on significantly shorter segments of speech compared to existing approaches, e.g., [4]. Second, an efficient implementation in the power cepstrum domain is proposed to reduce the computational demands of the approach. Finally, in the experiments we evaluate the proposed algorithm on real SSB HF recordings and also compare it to a state-of-the-art pitch tracking algorithm and a frequency difference estimation algorithm.

The paper is organized as follows: In Sec. II our features for carrier frequency difference estimation are derived, followed by Sec. III where we discuss details of the implementation in the power cepstrum domain. In Sec. IV and Sec. V the experimental results are discussed. The paper ends by drawing some conclusions in Sec. VI.

II. RAKE APPROACH

We are given a demodulated SSB HF signal, of which we assume that it has already been pre-processed by a speech activity detection unit, e.g., by the DNN-based approach from [13], such that only segments with active speakers are regarded in the following. Note, that these segments consist of voiced and unvoiced speech, as well as short pauses. In the spectral domain the pitch and its harmonics are clearly visible in a spectrogram, if the Short-time Objective Intelligibility (STOI) value [14] is above 0.5. However, many SSB transmissions have much worse STOI values and the pitch contours are occluded by noise or even completely erased, requiring noise robust algorithms and approaches (visit [15] for example signals).

In the following we propose to estimate the carrier frequency difference by a method that is based on locating the pitch and its harmonics in the noisy speech spectrogram. To this end it uses a filterbank with adjustable and time-varying center frequencies, that correspond to the fundamental frequency and its harmonics. One can view the filtering operation as a rake that is pulled in a filterbank with adjustable and time-varying center frequencies, difference by a method that is based on locating the pitch and its harmonics are clearly observable. To take account of this segments have only a very weak or even no pitch at all, although observed in our own experimental recordings, some audio

The summation in (2) gives a similar pitch detection feature as the Spectral Harmonics Distortion (SHC) used in the Y AAPT algorithm [9], whereby (2) is defined as a sum of logarithmic spectral values. The log-spectral domain formulation causes a dynamic range reduction and improves the numerical stability.

As reported in several publications, e.g., in [9], and also observed in our own experimental recordings, some audio segments have only a very weak or even no pitch at all, although the harmonics are clearly observable. To take account of this observation the weight of the pitch \( \omega(0, \nu) \) is only half of \( \omega(1, \nu) \), i.e., the weight of the first harmonic. Furthermore, all other harmonics are weighted with \( \omega(\tau, \nu) \approx \frac{1}{\tau} \), whereby all filters are designed in a triangular shape.

The summation in (2) gives a similar pitch detection feature as the Spectral Harmonics Distortion (SHC) used in the Y AAPT algorithm [9], whereby (2) is defined as a sum of logarithmic PSD values and SHC is a sum over a product of magnitude spectral values. The log-spectral domain formulation causes a dynamic range reduction and improves the numerical stability.

Since (2) extends the pitch tracking problem towards an open range search by introducing the unknown parameter \( f_D \), the computational complexity of the problem is increased by a factor proportional to the size \( |\Omega_{f_D}| \) of the set of

These values are weighted by factors \( \omega(\tau, \nu) \), which depend on the harmonic index \( \tau \) and the distance \( \nu \) to the filter center, and are summed by

\[
\Gamma(t, f_P(t), f_D) = \sum_{r=1}^{\tau_{max}} \sum_{\nu=-W}^{+W} \omega(\tau, \nu) \cdot \Psi(r; t, f_P(t), f_D). \tag{2}
\]

For each frequency difference \( f_D \) a different sequence of pitch values \( f_P = \{f_P(0), \ldots, f_P(T-1)\} \) is optimal in the sense that the summation of \( \Gamma(t, f_P(t), f_D) \) along \( t \) reaches a maximum. Stated differently, the maximization of (2) will yield an estimate of \( f_D \). This is achieved by the following three steps. First, for each time instance \( t \), the maximum across the possible pitch hypotheses \( f_P(t) \in [f_{P,\min}, f_{P,\max}] \) is computed:

\[
f_P'(t, f_D) = \argmax_{f_P(t)} \{\Gamma(t, f_P(t), f_D)\} \tag{3}
\]

\[
\Gamma'(t, f_D) = \Gamma(t, f_P'(t, f_D), f_D). \tag{4}
\]

\( \Gamma'(t, f_D) \) is the maximum log-energy value for a given demodulation shift hypotheses \( f_D \), and the corresponding pitch hypothesis is \( f_P'(t, f_D) \). Here, \( f_{P,\min} \) and \( f_{P,\max} \) denote the frequency bins corresponding to the assumed minimum (50 Hz) and maximum (400 Hz) pitch frequencies.

Next, a summation over time results in the accumulated log-energy per carrier frequency difference hypothesis \( f_D \):

\[
\widehat{\Gamma}(f_D) = \sum_{t=0}^{T-1} \Gamma'(t, f_D). \tag{5}
\]

Assuming a single speaker scenario, the maximum of \( \widehat{\Gamma}(f_D) \) is selected as the most likely hypotheses for the demodulation shift \( \widehat{f}_D \) with

\[
\widehat{f}_D = \argmax_{f_D \in \Omega_{f_D}} \{\widehat{\Gamma}(f_D)\} \tag{6}
\]

with \( \Omega_{f_D} \) denoting the set of candidate frequency differences, and the corresponding pitch hypotheses sequence is given by

\[
f_P = \{f_P(0, \widehat{f}_D), \ldots, f_P(T-1, \widehat{f}_D)\}. \tag{7}
\]
candidate values for the frequency difference. Hence, reducing the computational complexity becomes an important task which in our case is handled by interpreting (2) in the cepstral domain as shown in the next section.

### III. IMPLEMENTATION

The computationally expensive evaluation of the terms in (2) can be interpreted as a correlation of the logarithmic PSD values $\log(|X(t, f)|^2)$ with a filter function

$$h(f, f_P) = \sum_{\tau = 1}^{\text{max}} \sum_{\nu = -W}^W \omega(\tau, \nu) \cdot \gamma(f - \tau \cdot f_P(t) - \nu), \quad (8)$$

along the frequency axis, where $\gamma(.)$ denotes the unit impulse. This interpretation is similar to the harmonic sieves proposed in [16]. The correlation, which has to be carried out for all $f_P(t) \in [f_P, \min, f_P, \max]$, can be efficiently computed by applying a Fast Fourier Transformation (FFT), i.e., by moving to the power cepstral domain, and using the Overlap-Save-Method.

Fig. 2 shows a block diagram of the overall algorithm. This implementation is denoted as "Rake-PC" (Rake Power Cepstrum) in the following. The upper part of the figure illustrates the realization of the correlation of the log-PSD with the set of filters, where each filter corresponds to an assumed value of $f_P$, in the PSD domain. The resulting $\Gamma(t, f_P(t), f_D)$ depends on time frame $t$, the assumed pitch frequency $f_P(t)$, and the carrier frequency shift $f_D$. Next, the optimal value of the pitch is determined according to Eq. (3), followed by a summation along the time axis, Eq. (5). The resolution of the resulting $\Gamma(f_D)$ is limited by the STFT size, as the shift is given by its bin index. This can be overcome by interpolating the accumulated log-energy terms, e.g., by spline interpolation. The subsequent argmax operation from (6) yields the final estimate $f_D$, whose resolution is no longer limited by the FFT size.

Note, that the first maximum operation as stated in (3), is carried out independently for each time frame $t$, a clear shortcoming of the method, as it does not account for the inertia of the vocal cords, that results in smooth pitch trajectories. Introducing a-priori knowledge to account for the lowpass characteristics of the pitch trajectory, e.g., by using a simple first order Markov chain as proposed in [11], would improve the pitch tracking precision, however, at the cost of a significantly increased computational complexity.

The values of $f_D$ are quantized by the FFT resolution and the maximum search from (6) is restricted to the frequency bins that belong to the frequency range 0 Hz to 3500 Hz for a signal sampled at 8 kHz. The upper limit is motivated by the fact that a speech signal requires approximately a 500 Hz bandwidth to be intelligible and that the regarded harmonics have to fit in the considered frequency range. Signals with negative offsets $f_D$ are not considered because they are characterized by a significant signal loss of the lower frequencies and remain unintelligible without signal reconstruction approaches.

The availability of pitch trace estimates $f_P(t, f_D)$, $t = 0, \ldots, T - 1$, offers the opportunity to discard maxima in $\Gamma(f_D)$ that are caused by narrow-band digital transmissions instead of speech. As human speech is characterized by a time-variant pitch, while digital transmissions operate with a fixed frequency, the two can be discerned by the variance of $f_P(t, f_D)$. If it falls below a threshold, the detected signal is probably not speech and consequently discarded.

### IV. PITCH TRACKING EXPERIMENTS

To evaluate the proposed approach w.r.t. its capabilities of tracking the human pitch we used the PTDB-TUG database from [17] and compared our approach to the YAAPT algorithm implementation [9]. The results are given in Fig. 3. The Rake-PC pitch tracker achieves in more than 85% of all pitch containing speech segments a higher precision than the YAAPT algorithm. However, in the remaining 15% of the segments the performance stays way below YAAPT. This difference can be attributed to the sophisticated post-processing of YAAPT (multi pitch candidate selection process, non-linearities to restore missing pitches, application of temporal restrictions) which is missing in Rake-PC. If a Kalman filter is applied to the pitch

Figure 3: Cumulative density function (CDF) of pitch estimation error per frame on PTDB-TUG database [17].
with other ham radio stations. The HF signals are SSB band-limited to 2 kHz. SDR samples the data at 16 kHz. The difference the demodulation frequency of the transmitter and the receiver were selected to differ by values from the set \[ f_D = \{0, 100, 300, 500, 1000\} \]. Although the original speech samples have a sampling rate of 16 kHz, and the Kiwi-SDR samples the data at 12.001 Hz, the finally emitted data is band-limited to 2.7 kHz (International Telecommunication Union (ITU regulations) which introduces a loss of the upper frequencies in case of LSB transmission depending on the carrier frequency difference \( f_D \). The data set has a total size of 23:31 hours of which 3:28 hours contain speech activity.

A. Carrier Frequency Difference Estimation

Fig. 4 the error between the estimated difference \( \hat{f}_D \) and the ground truth difference is depicted. For this experiment the length of the speech segments was between 10 s and 27 s. The system works reliable with errors below ±5 Hz, which is an error that is not perceivable by humans [3].

For shorter speech segments the error increases as can be seen in Fig. 5, where we grouped the estimation errors in five classes. In that figure we compared our approach to the harmonic/spectral envelope approach of [4], which we implemented on our own since no open source implementation was available. It can be observed that the proposed approach achieves lower estimation errors, both on short and longer speech utterances.

B. Parallel speakers and harmonic errors

A small amount of our recordings include the special case of a concurrent speaker at a higher frequency. This is a challenging,

\[
\text{Estimated offset error}[\text{Hz}]
\]

V. EXPERIMENTS ON HAM RADIO DATA

We have set up a transmission system between our amateur radio station in Paderborn and several other distant ham radio stations across Europe, transmitting utterances from the LibriSpeech corpus [18]. Kiwi-software defined radio (SDR) devices [19] at the distant stations were utilized to demodulate the received SSB HF signals and send the recorded audio signals back to our servers via a websocket connection. Audio markers had been added to the signal to allow for an automated time alignment between the transmitted and received signals, easing the annotation and segmentation of the data [15].

For the transmissions a beacon, callsign DB0UPB, was used, which was supervised by a human to avoid interference with other ham radio stations. The HF signals are SSB modulated using the Lower Side Band (LSB) with a bandwidth of 2.7 kHz at carrier frequencies of 7.06 MHz – 7.063 MHz and 3.6 MHz – 3.62 MHz. To simulate a carrier frequency difference the demodulation frequency of the transmitter and the receiver were selected to differ by values from the set \( f_D = \{0, 100, 300, 500, 1000\} \). Although the original speech samples have a sampling rate of 16 kHz, and the Kiwi-SDR samples the data at 12.001 Hz, the finally emitted data is band-limited to 2.7 kHz (International Telecommunication Union (ITU regulations) which introduces a loss of the upper frequencies in case of LSB transmission depending on the carrier frequency difference \( f_D \). The data set has a total size of 23:31 hours of which 3:28 hours contain speech activity.

A. Carrier Frequency Difference Estimation

Fig. 4 the error between the estimated difference \( \hat{f}_D \) and the ground truth difference is depicted. For this experiment the length of the speech segments was between 10 s and 27 s. The system works reliable with errors below ±5 Hz, which is an error that is not perceivable by humans [3].

For shorter speech segments the error increases as can be seen in Fig. 5, where we grouped the estimation errors in five classes. In that figure we compared our approach to the harmonic/spectral envelope approach of [4], which we implemented on our own since no open source implementation was available. It can be observed that the proposed approach achieves lower estimation errors, both on short and longer speech utterances.

B. Parallel speakers and harmonic errors

A small amount of our recordings include the special case of a concurrent speaker at a higher frequency. This is a challenging,
however likely scenario to be encountered in practice. Fig. 6 depicts the accumulated logarithmic energy $\hat{\Gamma}(f_D)$, Eq. (5), versus candidate frequency difference $f_D$. Both, the speaker at 100 Hz and the interfering crosstalker at 1098 Hz are visible as maxima in the accumulated log-energy. Also two secondary maxima are visible next to the crosstalker which we attribute to harmonics/subharmonics and a possible non-linearity in the transmission system. So extending the Rake-PC towards concurrent speaker tracking and identification seems to be possible, similar to multi-speaker tracking in diarization [20] or localization tasks [16].

C. Processing time

In Fig. 7 the real time factors of the proposed approach, our implementation of [4] and the reference implementation of the YAAPT algorithm from [9] are given. The implementation following Fig. 2 ("Rake-PC (Single Core)") improves the real time factor significantly compared to the direct implementation ("Rake (Single Core)"). The overall processing time can be further reduced by a straightforward parallel implementation ("Rake-PC (Multi Core)"). For a FFT size of 2048 Rake-PC has a similar real time factor as [4] and [9].

![Figure 7: Real time factors for different approaches and FFT sizes, including single and multi core implementation for a block shift of 20 ms. (AMD Ryzen 5 3600, 6-Core, 32GB RAM, Matlab)](image)

VI. CONCLUSIONS

In this paper we have presented an approach that estimates frequency differences between the mixing oscillator in the HF transmitter, that moves the baseband signal to the carrier frequency, and the oscillator in the receiver that converts the radio signal back to baseband. It is based on tracking the pitch and its harmonics in the received baseband speech signal in an open range search method. Experiments on real data from HF transmissions show promising performance, both in terms of precision and computational complexity.
