Abstract
Background: Lymph node yield (LNY) was implemented in the stratification of papillary thyroid cancer (PTC) patients. The effect of LNY may be related to the extent of surgery. This study aims to identify influencing factors for LNY in central compartment neck dissection (CND).

Methods: Data of 13 712 consecutive PTC patients were analyzed retrospectively. Risk factors for LNY in CND and distribution characteristics of LNY were evaluated. Its relationship with prognosis was studied in another cohort of 136 cases.

Results: LNY in therapeutic CND was significantly higher than prophylactic CND (Unilateral: 5.55 ± 3.79 vs 3.41 ± 2.77; Bilateral: 8.90 ± 5.10 vs 6.47 ± 4.17, P < .001). Other independent factors included extranodal extension (ETE), tumor size, and concurrent Hashimoto’s thyroiditis. The inconsistency distribution of LNY in bilateral CND was associated with preoperative and intraoperative assessment. Patients with significant difference between major and minor LNY suffered from poorer prognosis (10y-RFS: 58.3% vs 92.0%; HR = 6.719, 95% CI, P < .0001).

Conclusions: CND surgical procedure, ETE, and Hashimoto’s thyroiditis were independent factors of LNY. Inconsistent distribution of LNY was associated with prognosis of bilateral PTC patients. The impact of preoperative and intraoperative assessment on the actual extent of CND can be used to explain the relationship between LNY and PTC prognosis.

Keywords
central neck dissection, lymph node yield, papillary thyroid cancer, surgical assessment
Thyroid cancer is the most common neoplasm of endocrine system.\textsuperscript{1} Papillary thyroid cancer (PTC) accounts for more than 90\% of all thyroid malignancies. Despite its inert biological behavior and good prognosis, lymph node metastasis in PTC is not rare, which is also a prognostic factor of recurrence.\textsuperscript{2} Complete resection of the primary tumor and regional lymph node metastases is regarded as the most critical treatment for PTC.

The specific features of lymph node metastases, including the number of positive lymph nodes (PLN), lymph node yield (LNY), lymph node ratio (LNR), and extranodal extension (ENE) have been suggested to serve as stratification parameters for patients with lymph node metastasis.\textsuperscript{3-11} PLN, LNR, and ENE all relate to tumor progression directly, consequently affecting PTC prognosis. However, this explanation is not applicable for LNY.

For differentiated thyroid cancer (DTC), the relationship between LNY and disease prognosis has already been well established.\textsuperscript{4,5,12,13} Terry Hyslop et al\textsuperscript{14} presented a statistical model to estimate the risk of false-negative lymph node dissection and occult nodal disease. LNY can reflect the actual extent of lymph node dissection. Inadequate extent of lymph node dissection may cause residual remnants of metastases, thus compromise patient prognosis.\textsuperscript{15}

The real extent of dissection cannot be objectively evaluated, forcing us to turn to the indirect reflection of surgical extend, which is LNY. Based on the preoperative and intraoperative evaluation, a surgeon may form his own perception of the disease and adjust the actual extent of surgery. We aim to focus on LNY and its influencing factors in central compartment lymph node dissection (CND) in this study.

Clinicopathological data (age, gender, maximum size of the largest lesion, ETE, multifocality, concurrent Hashimoto’s thyroiditis, and lymph node metastasis) were collected. ETE of the primary tumor consisted of gross and microscopic ETE. Multifocal primary lesions were defined as two or more malignant lesions found within thyroid glands. CND were divided into prophylactic and therapeutic CND. The judging criteria included: (a) whether or not suspicious lymph node was detected by preoperative US and (b) therapeutic CND was routinely performed in patients diagnosed with cN1b. We also defined a new term, “Semi-therapeutic CND” in the study. It refers to CND performed in patients with inconclusive enlarged lymph nodes detected by preoperative US.

We further collected clinical data from an independent cohort consisting of 136 patients with bilateral PTC and received bilateral CND during 2000-2006 at our hospital. Prognosis information was all intact. A small portion of these patients overlaps the previous cohort. The recurrence-free survival (RFS) was defined as the duration from the date of diagnosis by operation to the date of disease recurrence or progression. Patients with no event were censored on the date of the last follow-up.
proportional hazards regression models. Statistical analyses were performed using SPSS 22.0 (IBM Corp). Kaplan-Meier survival curves were drawn by GraphPad Prism 6.01 (GraphPad Software). A two-sided \( P \) value < .05 was considered as statistically significant.

3 | RESULTS

3.1 | Patient characteristics

The study cohort consisted of 13 712 patients, including 10 214 women with age range of 15-88 years (mean 43.89 ± 11.87). Lobectomy or any other procedure less than total thyroidectomy was performed in 10 328 patients while 2733 patients underwent total thyroidectomy. CND was routinely performed in all patients. Therapeutic lateral lymph node dissection (LLND) was performed in 2285 patients. Incidence of positive lymph node metastasis in central and lateral compartment were 47.0% and 15.7%, respectively. The mean number of harvested central lymph nodes was 4.44 ± 3.71 (range 0-37), and 26.14 ± 14.89 (range 5-123) in lateral lymph nodes. The characteristics of these patients are listed in Table 1.

3.2 | Impact of CND surgical procedure on number of LNY in central compartment

All patients were divided into three groups: (a) therapeutic CND group: patients diagnosed with cN1a by US and patients who needed LLND; (b) prophylactic CND group: patients who had no positive findings (cN0); and (c) semi-prophylactic CND group: patients who were detected with indeterminate enlarged lymph nodes. As are listed in Table 2, regardless of unilateral or bilateral CND, patients with therapeutic CND had significantly higher LNY than prophylactic group. LNY of therapeutic group was also higher than semi-prophylactic group, however not significantly.

3.3 | Impact of pathological features on LNY in CND

Univariate analysis in this study showed that ETE, tumor size, and concurrent Hashimoto's thyroiditis were associated with LNY in CND (Table 3). Although no difference of LNY between negative and minimal ETE group was detected, LNY in the gross ETE group was significantly higher than the above two (Unilateral: 5.89 ± 3.76; Bilateral: 8.90 ± 5.31, \( P < .001 \)). Furthermore, multivariate regression analysis revealed that CND surgical procedure, ETE, and Hashimoto's thyroiditis were independent factors of LNY (Table 4).

### Table 1: Clinical and pathologic characteristics of 13 712 PTC patients

| Clinical features                                      | Number (N) | Percentage |
|--------------------------------------------------------|------------|------------|
| Age at first diagnosis                                 |            |            |
| Mean (y)                                               | 43.89 ± 11.87 |            |
| ≤55 y                                                  | 10 978 (80.1) |            |
| > 55 y                                                 | 2734 (19.9)  |            |
| Gender                                                 |            |            |
| Male                                                    | 3498 (25.5) |            |
| Female                                                  | 10 214 (74.5) |            |
| Tumor size                                             |            |            |
| Mean (cm)                                              | 1.11 ± 0.86 |            |
| ≤10 mm                                                 | 7278 (53.1)  |            |
| > 10 mm                                                | 6434 (46.9)  |            |
| ETE                                                     |            |            |
| Negative                                               | 12 283 (89.6) |            |
| Minimal extension                                       | 1210 (8.8) |            |
| Advanced disease                                        | 219 (1.6) |            |
| Multifocal (%)                                          | 3876 (28.3) |            |

| Central neck lymph node metastasis (%)                  | 6440 (47.0) |            |
| Lateral neck lymph node metastasis (%)                  | 2149 (15.7) |            |

Abbreviations: CND, central compartment lymph node dissection; ETE, extrathyroidal extension.

3.4 | Characteristics of LNY in patients with bilateral CND

We identified 2246 patients underwent total thyroidectomy plus bilateral CND. For the convenience of this analysis, the side with more LNY was defined as the major side, and the less as the minor side. Accordingly, 456 patients had a major LNY less than 2 while their minor LNY was mostly 0. These patients were excluded considering difficulty of following analysis. Eventually, 1790 patients entered the analysis phase.

Difference and ratio relationships of LNY between the major and minor side are presented in Figure 1. When the major LNY was more than 6, only 18.9% of the patients has the same number of minor LNY. In 48.7% and 13.6% of the patients, the difference between major and minor LNY was ≥3 and ≥6, respectively. In terms of LNY ratio, 38.3% of the patients had a major LNY which was 2 times higher
than the minor LNY, and 10.6% had a LNY ratio of more than 4. The proportion would rise to 41.0% and 11.4%, respectively, if 120 patients with minor LNY of 0 were excluded (Table S1).

Patients were then divided into three groups: (a) bilateral prophylactic CND; (b) unilateral therapeutic and contralateral prophylactic CND; and (c) bilateral therapeutic CND. In group 3, patients whose LNY difference were less than 2 and greater than 6 accounted for 58.6% and 9.7% of the total population, respectively. Similar data can be seen in group 1 (56.7% and 11.0%). However, it was significantly different in group 2, with the corresponding data of 33.9% and 22.3%, respectively. Similar results were also observed in the ratio analysis (Table 5). Bilateral LNY in patients of group 2 had the greatest degree of variation.

### 3.5 Impact of LNY pattern in patients with bilateral CND on survival

In a considerable portion of patients with bilateral CND, the differences in LNY between the major and minor side
was significant. Data from 136 bilateral PTC patients with bilateral CND during 2000 to 2006 were collected. The average follow-up period was 107 months (range from 8 to 201 months). Detailed information of these cases is listed in Table S2. At the endpoint of our follow-up, 24 patients suffered from recurrent disease. Among them, 11 cases had recurrent sites in the lateral neck (level II-V), 7 cases in the level VI and thyroid bed, 4 cases in both of lateral and central compartment and 2 cases with distant metastasis.

We then divided all cases into two groups according to LNY disparity: (1) non-significant group with difference value (D-value) \( \leq 3 \) or ratio value (R-value) <2 and (2) significant group with D-value >3 and R-value \( \geq 2 \). In the 24 relapsed patients, 17 (70.8%) were classified as significant group. From Kaplan-Meier survival plots (Figure 2), we observed a significant worse prognosis in this group. The calculated 5y and 10y-RFS was 96.0% and 92.0% for non-significant group, as well as 80.6% and 58.3% for significant group. This result was also supported by Cox regression analysis after adjusted by age, gender, T stage, and local metastatic status (HR = 6.719, 95% CI: 2.789-16.789, \( P < .0001 \)), indicating LNY distribution of CND is an independent factor of RFS in bilateral PTC patients.
Recurrence characteristics of the 17 relapsed cases are summarized in Table 6. Of these 17 cases, the central neck compartment was involved in 10 cases (58.8%) and the shortest RFS time was 31m, indicating a direct relationship between the extent of CND on the minor side and disease recurrence in PTC patients.

**TABLE 6** Clinical characteristics of 17 recurrence cases with significantly diverse LNY in major and minor side

| Case | Age | Gender | Major side (PLN/LNY) | Minor side (PLN/LNY) | Location of recurrence lesion | Recurrence-free survival (m) |
|------|-----|--------|----------------------|----------------------|-------------------------------|-----------------------------|
| 1    | 24  | Female | 9/9                  | 3/3                  | Level VI in major side        | 8                           |
|      |     |        |                      |                      | Lateral neck in minor side    |                             |
| 2    | 51  | Male   | 4/6                  | 0/0                  | Lateral neck in major side    | 96                          |
| 3    | 49  | Male   | 8/11                 | 3/3                  | Lateral neck in minor side    | 48                          |
| 4    | 33  | Female | 12/16                | 1/7                  | Level VI and lateral neck in minor side | 120                        |
| 5    | 24  | Male   | 12/13                | 0/0                  | Level VI and lateral neck in minor side | 49                         |
| 6    | 35  | Male   | 3/4                  | 0/0                  | Level VI in minor side        | 73                          |
| 7    | 42  | Female | 5/8                  | 2/2                  | Level VI in both sides        | 58                          |
| 8    | 15  | Male   | 7/7                  | 3/3                  | Level VI in both sides        | 63                          |
| 9    | 27  | Female | 4/14                 | 2/4                  | Lateral neck in major side    | 61                          |
| 10   | 28  | Female | 13/15                | 5/5                  | Lateral neck in major side    | 66                          |
| 11   | 37  | Female | 11/13                | 3/3                  | Level VI and lateral neck in minor side | 31                        |
| 12   | 46  | Male   | 7/14                 | 6/8                  | Level VI in both sides        | 36                          |
| 13   | 55  | Female | 3/8                  | 1/3                  | Level VI in both sides and thyroid cartilage | 62                        |
| 14   | 52  | Female | 3/14                 | 0/1                  | Lateral neck in major side    | 69                          |
| 15   | 22  | Female | 6/9                  | 2/4                  | Level VI in minor side        | 56                          |
| 16   | 50  | Female | 3/5                  | 1/1                  | Lung and subcutaneous metastasis | 38                      |
| 17   | 59  | Female | 7/7                  | 2/2                  | Mass in central neck with trachea, larynx, prevertebral invasions | 99                      |

Abbreviations: LNY, lymph node yield; PLN, positive lymph node.

**FIGURE 2** Kaplan-Meier plots of recurrence-free survival. The survival plot grouped by VI pattern indicated a significant difference of RFS between patients with different distributional characteristics of bilateral LNY ($P = .001$). VI pattern 1: non-significant group with D-value $\leq 3$ or R-value $<2$; VI pattern 2: significant group with D-value $>3$ and R-value $\geq 2$.

4 DISCUSSION

The relationship between LNY and the prognosis of PTC has been well established by previous studies. Higher LNY is associated with a lower recurrent rate, regardless of CND or LND. The risk factors of LNY could be summarized into three categories: (a) individual factor. Anatomic difference between individuals. According to Tavares MR et al., the normal number of lymph nodes in the central neck compartment varies from 2 to 44. (b) Pathological factor. Under the circumstance of small lymph nodes and relatively large dissection specimen, lymph nodes may be hard to distinguish and thus cloud the count of LNY. (c) Surgical factor. LNY is an indirect reflection of the extent of neck dissection. Therefore, surgical factor has the highest correlation with clinical practice.

Difference in LNY can be interpreted in two ways, the CND was either expanded or narrowed. It is reasonable to assume that some surgeons would expand the scope of CND in order to achieve the best curative effect. Theoretically, an enlarged CND should lead to the same prognosis as that of a standard CND. However, a significantly higher risk of recurrence was noticed in imbalanced bilateral CND patients in our study, indicating the difference of LNY was mainly caused by the narrowing of CND.

We have analyzed several suspicious factors that may alter a surgeon’s perception of the disease, causing...
variation in the completeness of CND and further affect LNY. According to our data, we have reached the following important conclusions: (a) Preoperative factors. When suspicious lymph nodes were detected by US (cN1), LNY obtained by therapeutic CND was significantly higher than prophylactic surgery. (b) Intraoperative factors. Among all analyzed pathological characteristics, gross ETE and Hashimoto’s thyroiditis were the only two independent factors. (c) For patients undergoing bilateral CND, it was common to observe LNY disparity on both sides. Notably, patients with greater LNY difference had a significantly higher risk of recurrence.

The actual extent of CND, as reflected by LNY, was varied due to the purpose of CND. The appearance of the tumor and lymph nodes presented during operation are more intuitive. Our study showed in patients with minimal ETE, LNY was almost the same as the patients without any ETE. However, significantly increased LNY was detected when gross ETE occurred. Tumors with gross ETE were more easily observed by the naked eye, causing surgeons to expand CND extent, which can also be applied in Hashimoto’s thyroiditis where hyperplastic lymph nodes appeared. However, the long-term inflammation itself may increase the number of regional lymph node.19,20

We then tried to perform a similar analysis using SEER database. As SEER did not separate CND from other kinds of neck dissections, we could only include patients with staging N0 and N1a. (N = 8974). CND surgical procedure, Hashimoto’s thyroiditis, and any other related characteristics were insufficient in the SEER database. Therefore, we only conducted a univariate analysis of ETE and tumor size. As listed in Table S3, both factors were significantly associated with LNY.

The results of bilateral CND and LNY should be interpreted with caution. The quantity of lymph nodes in the left and right side of central neck compartment is anatomically different. Also, the borderline which separate the left and right central compartment is simply a man-made cut. Therefore, the variation of LNY caused by a surgeon’s distribution of the lymph nodes was treated as a random factor. Similarly, negligence in pathologic reports was considered as another random factor. All the mentioned factors should have no effect on prognosis in theory. However, our results showed that prophylactic plus therapeutic CND caused an increased difference of LNY between two sides and was accompanied by a significant reduction in RFS, indicating a true divergence in patient prognosis and emphasizing the influence of the surgical extent. CND is a known risk factor for injuries of recurrent laryngeal nerve and parathyroid gland. Upon that, bilateral CND may lead to permanent tracheotomy and hypocalcemia.21 To avoid complications, the actual extent of CND on the prophylactic side may be reduced if no other risk factors were observed.

Our study has some limitations. First, the routine surgical approach in our hospital is different from most of other centers in the world. Second, for 136 bilateral PTC patients with prognostic analysis, information of RAI was insufficient, which may affect the related results. Third, because of limited follow-up data, we did not analyze the relationship between LNY and prognosis in the entire patient population. Fourth, it was a single-institution retrospective study, results of which need to be confirmed by more evidence in the future.

In conclusion, by analyzing the data from a relatively large patient sample, we found that the CND procedure, ETE of primary tumor, and concurrent Hashimoto’s thyroiditis were independent factors of LNY. In PTC patients with bilateral CND, LNY in one side was often higher than that of the other. This phenomenon was also associated with the CND procedure and accompanied with a significantly increased risk of recurrence. These results suggest that preoperative and intraoperative assessment suggesting the patient is at higher risk impacts on the actual extent of CND, which may explain the relationship between LNY and the prognosis of PTC patients.
