Abstract. The present work deals with a theoretical research on the emission and radiation properties of a dipole emitter source close to a dimer graphene plasmonic antenna. Modification of the radiation and the quantum efficiencies resulting from varying the position of the emitter and the orientation of its dipole moment are calculated by using a rigorous electromagnetic method based on Green’s second identity. Large enhancements in the emission and the radiation of the emitter occur due to the coupling with the antenna surface plasmons in the spectral region from $\approx 4\text{THz}$ to $\approx 15\text{THz}$. Our results show that the radiation efficiency can be enhanced by four orders of magnitude and that the quantum efficiency reaches values close to 0.8 when the emission frequency coincides with one of the resonant dipolar frequencies. On the other hand, these quantities can be reduced in a great measure at a specific frequency for a given emitter location. We present calculations of the near–field distribution and the far field intensity which reveal the role of the plasmonic antenna resonance in the emitter enhanced radiation. We show that the spectral region where the radiation is enhanced can be chosen over a wide range by varying the chemical potential of graphene from 0.2eV to 1eV.

1. Introduction

The coherent interplay between an individual optical emitter and the electromagnetic fields scattered back to the emitter’s site by the environment boundaries acts to drive the emitter and as a consequence the light emission can be largely altered. For instance, coupling the optical emitter to confined electromagnetic modes, such as guided modes or surface plasmons (SPs), is possible to enhance the spontaneous emission rate several orders of magnitude relative to the case in which the same emitter is localized in an unbounded medium. This property, known as Purcell effect \[1, 2\], has been used to improve the efficiency of single photon sources \[3\] as well as to reduce the lasing threshold in plasmonic lasers \[4, 5\].

Based on the same physical effect, plasmonic antennas are subwavelength architectures capable to confine the electromagnetic field in a reduced region of the space by localized surface plasmons (LSPs) excitation, leading to an enhancement in the radiative and non-radiative emission of an emitter placed in that region \[6, 7, 8, 9, 10, 11\]. One of the major challenges for most of applications, such as fluorescence or surface enhanced Raman spectroscopy (SERS) platforms \[12, 13, 14\], is to reach an efficient radiative outcoupling of LSPs into photons, which allows an increase of the radiative emission rate relative to the non-radiative emission rate. This property has been obtained for some geometries, such as dipole or bowtie antennas \[15, 16, 17\], stand out for creating a high density of radiative states on their gap region. More recently, its has been demonstrated that a high radiation efficiency together with a directionality improvement take place on metallic nanopatch antenna platforms \[18, 19\].

Apart from noble metals, the plasmonic materials most frequently used for plasmonic antenna applications, recent advances have created other plasmonic materials with lower losses and greater confinement of the electromagnetic field, such as metal–alloys, heavily doped wide–band semiconductors, and graphene \[20\]. The electronic linear band structure of graphene makes a plasmon mass depending on the Fermi–level position and consequently electrically (or magnetically) tunable SPs are supported by graphene from microwaves to the mid–infrared regimes \[21, 22\]. Several alternative structures for confining of the incident beam in the realm of graphene plasmonic have been studied in THz regime \[23, 24, 25, 26, 27, 28, 29, 30\]. In particular, the high SP confinement on a graphene monolayer leads to two main properties: a small SP wavelength and an improvement in the electromagnetic energy density. The former deals with the possibility to build more smaller plasmonic constituent elements and the second is related with the large enhancement of the decay rate of an emitter via the Purcell effect \[31, 32, 33\]. These features positioned the graphene as a promising platform to the development of controllable plasmonic devices \[34, 35, 36\], in particular of a new generation of antennas from microwaves to the mid–infrared regimes \[37\] which comprises a crossover between electronic and optics. In this way, graphene antennas have found applications as sensors, \(i.e.,\) to capture an impinging wave in order to feed oscillating dipoles \[38\], or as emitters, where the enhanced density of radiating states enables an excitation of oscillating dipoles \[39\]. In fact, graphene antennas have been proposed as reconfigurable transceivers in the THz domain \[40\].

This paper deals with the study about the control of the radiative emission of a single emitter placed in the environment of a graphene plasmonic antenna. We focus on the dipole geometry in which the antenna consists of two identical elements facing each other (nearly in contact). We consider each of these constituent elements consisting of a wire cylinder (arbitrary section) wrapped with a graphene sheet. The calculation of relevant magnitudes is carried out by using the Green function surface integral method (GSIM) \[41, 42, 43\], which enables to solve the scattering problem for structures with a complex shape. The GSIM has been used by us to deal with the electromagnetic scattering of an optical emitter inside a graphene coated wire of arbitrary section \[44\].

We have considered the graphene as an infinitesimally thin, two–sided layer with a frequency–dependent surface conductivity given by the Kubo formula \[45\]. This approach is particularly appropriate and, as it has been shown in \[46\], it matches the results in remarkable optical experiments.

This paper is organized as follows. First, in Section \[2\] we develop the GSIM formalism providing expressions for the electromagnetic field scattered by a line dipole source placed, with an arbitrary orientation, near a graphene plasmonic antenna. This field is expressed in terms of two unknown source functions evaluated on the graphene layer, one related to the field exterior to the antenna and the other related to its normal derivative. By using GSIM, in Section \[3\]
the wire substrates are characterized by constitutive
\( \varepsilon \) and \( \Gamma \), the performance of the dimer antenna formed. Finally, we include a second graphene wire and investigate for a graphene dimer antenna. Even though the
we calculate the radiative and the quantum efficiencies for a graphene dimer antenna. Even though the above formalism has been developed considering two scatter elements (the two graphene wire composing the antenna), for a better understanding, in a first step we deal with the single graphene wire problem. We then include a second graphene wire and investigate the performance of the dimer antenna formed. Finally, concluding remarks are provided in Section 4. The Gaussian system of units is used and an exp\((-i \omega t)\) time-dependence is implicit throughout the paper, with \( \omega \) as the angular frequency, \( t \) as the time, and \( i = \sqrt{-1} \). The symbols Re and Im are respectively used for denoting the real and imaginary parts of a complex quantity.

2. Theory

2.1. Surface integral equations of the electromagnetic field scattered by a dipole emitter

We consider the scattering problem of a line dipole source in the proximity of two graphene coated wire cylinders (figure 1). We assume that the cylinders and the dipole line axis lie along the \( \hat{z} \) axis. The current density of the electric dipole is

\[
\mathbf{j}_e(\mathbf{r}) = -i \omega \mathbf{p} \delta(\mathbf{r} - \mathbf{r}_s^e). 
\]  

(1)

The cross section of the wires are defined by planar curves described by vector valued functions \( \Gamma_2(t) = x_2(t)\hat{x} + y_2(t)\hat{y} \) and \( \Gamma_3(t) = x_3(t)\hat{x} + y_3(t)\hat{y} \) and the wire substrates are characterized by constitutive parameters \( \varepsilon_2, \mu_2 \) and \( \varepsilon_3, \mu_3 \). The wires are embedded in a transparent medium with constitutive parameters \( \varepsilon_1, \mu_1 \). When the line source with a dipole moment \( \mathbf{p} = p[\cos \alpha \hat{x} + \sin \alpha \hat{y}] \) is placed in medium 1 (\( \alpha \) is the angle between the dipole moment and the \( \hat{x} \) axis), the magnetic field is along the \( \hat{z} \) axis (\( \mathbf{H}(\mathbf{r}) = \varphi(\mathbf{r})\hat{z} \)). The wave equation for the magnetic field has the form

\[
\nabla^2 \varphi_j(\mathbf{r}) + k_j^2 \varphi_j(\mathbf{r}) = g_j(\mathbf{r}, \mathbf{r}_s^e),
\]

(2)

where subscripts \( j = 1, 2, 3 \) is used to denote the wire substrates (medium 2 and medium 3) and the exterior region (medium 1) to boundary wires, respectively, \( k_j = k_0 \sqrt{\varepsilon_j \mu_j} \), \( k_0 = \omega / c \) is the modulus of the photon wave vector in vacuum, \( \omega \) is the angular frequency, \( c \) is the vacuum speed of light, \( g_1(\mathbf{r}, \mathbf{r}_s^e) = -4 \pi i k_0 \mathbf{p} \times \nabla \delta(\mathbf{r} - \mathbf{r}_s^e) \), \( g_2(\mathbf{r}, \mathbf{r}_s^e) = g_3(\mathbf{r}, \mathbf{r}_s^e) = 0 \) and \( \mathbf{r}_s^e \) denotes the position of the line source. To solve Eq. (2), we transform it into a boundary integral equation using the GSIM as explained in [4]. Using Eq. (2) in the exterior region, the magnetic field \( \varphi(\mathbf{r}) \) can be written as

\[
\varphi_{inc}(\mathbf{r}) + \sum_{j=2}^{3} \frac{1}{4\pi} \int_{\Gamma_j} \left[ \frac{\partial G_j(\mathbf{r}, \mathbf{r}_s^e)}{\partial n_{\tau_j}} \varphi_1(\mathbf{r}_s^e) - G_1(\mathbf{r}, \mathbf{r}_s^e) \frac{\partial \varphi_j(\mathbf{r}_s^e)}{\partial n_{\tau_j}} \right] d\Gamma_j
\]

(3)

Similarly, inside the wires (regions 2 and 3) the field take the form

\[
-\frac{1}{4\pi} \int_{\Gamma_j} \left[ \frac{\partial G_j(\mathbf{r}, \mathbf{r}_s^e)}{\partial n_{\tau_j}} \varphi_j(\mathbf{r}_s^e) - G_j(\mathbf{r}, \mathbf{r}_s^e) \frac{\partial \varphi_j(\mathbf{r}_s^e)}{\partial n_{\tau_j}} \right] d\Gamma_j
\]

(6)

where \( G_j(\mathbf{r}, \mathbf{r}_s^e) \) is the Green function in the interior region \( j \), \( \varphi_j(\mathbf{r}) \) if \( \mathbf{r} \) is inside the interior region \( j \), \( \varphi_j(\mathbf{r}) \) if \( \mathbf{r} \) is outside the interior region \( j \), and \( \varphi_{inc}(\mathbf{r}) \) is the incident field.
provide two additional relationships between the fields and their normal derivatives at the boundary of the wires, allowing us to express $\varphi_j, \partial \varphi_j / \partial n_j$ ($j = 2, 3$) in terms of $\varphi_1$ and $\partial \varphi_1 / \partial n_1$. By evaluating the first of Eq. (3) and the second of Eq. (6) at the boundaries $\Gamma_j$ and using the continuity conditions across them, we obtain a set of coupled integral equations:

$$
\varphi_1(\vec{r}_1') = \varphi_{\text{inc}}(\vec{r}_1')
$$

$$
+ \sum_{j=1}^{3} \frac{1}{4\pi} \int_{\Gamma_j} \left[ \frac{\partial G_1(\vec{r}_1', \vec{r}_j)}{\partial n_j} \varphi_1(\vec{r}_j) - G_1(\vec{r}_1', \vec{r}_j) \frac{\partial \varphi_1(\vec{r}_j)}{\partial n_j} \right] \, ds_j,
$$

where $l = 2, 3$ indicates the region in which the vector $\vec{r}$ is taken, and

$$
0 = -\frac{1}{4\pi} \int_{\Gamma_j} \left[ \frac{\partial G_2(\vec{r}_2', \vec{r}_j)}{\partial n_j} \varphi_1(\vec{r}_j) - G_2(\vec{r}_2', \vec{r}_j) \frac{\partial \varphi_2(\vec{r}_j)}{\partial n_j} \right] \, ds_j,
$$

where $l, j = 2, 3$.

It is worth noting that the four Eqs. (9) and (10) are reduced to the set of two equations obtained in [44] for the single wire case, i.e., when the system is composed of only one graphene wire element whose cross section is defined by a vector valued function $\Gamma_2$, by fixing $j = l = 2$,

$$
\varphi_1(\vec{r}_1') = \varphi_{\text{inc}}(\vec{r}_1')
$$

$$
+ \frac{1}{4\pi} \int_{\Gamma_2} \left[ \frac{\partial G_1(\vec{r}_1', \vec{r}_2)}{\partial n_2} \varphi_1(\vec{r}_2) - G_1(\vec{r}_1', \vec{r}_2) \frac{\partial \varphi_1(\vec{r}_2)}{\partial n_2} \right] \, ds_2,
$$

$$
0 = -\frac{1}{4\pi} \int_{\Gamma_2} \left[ \frac{\partial G_2(\vec{r}_2', \vec{r}_2)}{\partial n_2} \varphi_1(\vec{r}_2) - G_2(\vec{r}_2', \vec{r}_2) \frac{\partial \varphi_2(\vec{r}_2)}{\partial n_2} \right] \, ds_2.
$$

The coupled integral equations (9) and (10), or Eq. (11) in case of the single wire system, are converted into matrix equations which are solved numerically (see [44] and references therein). Once the functions $\varphi_1(\vec{r}_1')$ and $\partial \varphi_1(\vec{r}_1')$ are determined, the scattered field, given by the first of Eqs. (9) and (10) can be calculated at every point in the exterior and interior regions.

### 2.2. Emitted and radiated powers

The time–averaged power $P$ emitted by the dipolar line source can be calculated from the integral of the normal component of the complex Poynting vector flux through an imaginary cylinder of length $L$ and radius $\rho_0$ that encloses the system (see Figure 1)

$$
P = -\frac{1}{2} \int_{A_s} \Re \left\{ \vec{J}_s^* \cdot \vec{E} \right\} \, da,
$$

where $A_s$ encloses the source, $da = \rho_0 \, d\phi_0 \, d\rho_s$ and $\vec{j}_s$ represents the source density current. Introducing the value of the current in Eq. (11), we obtain

$$
P = \frac{\omega L}{2} \text{Im} \left\{ \vec{p}^* \cdot \vec{E}(r_s^*) \right\}
$$

where the field $\vec{E}$ is evaluated at the dipole position $r_s^*$. For an electric dipole we have

$$
\vec{E}(\vec{r}) = E_{inc}(\vec{r}) + \vec{E}_s(\vec{r})
$$

where $\vec{E}_{inc}$ and $\vec{E}_s$ are the primary dipole field and the scattered field, respectively. Inserting Eq. (14) into Eq. (13), we obtain the emitted power normalized with respect to the rate in absence of the graphene wire

$$
\gamma = \frac{P_{inc}}{P_{inc}^0 = \frac{\pi k_0 P c L}{4}}
$$

where $P_{inc} = \frac{\pi k_0 P c L}{4}$ is the total power radiated by an electric dipole in the unbounded medium 1 [44] 45. By using the Ampere–Maxwell equation the relation between the components of the electric field and the $z$–component of the magnetic field is derived, $E_j = -\frac{i k_0 \varepsilon}{\varepsilon k_0} \nabla \times \hat{z} \varphi_j$ ($j = 1, 2, 3$), and the components of the electric field scattered back at the dipole position $r_s^*$ are calculated as

$$
E_{s,x}(r_s^*) = \frac{1}{4\pi k_0} \int \sum_{j=2}^{3} \int_{\Gamma_j} \left[ \frac{\partial G_1(\vec{r}_2, \vec{r}_j)}{\partial y \delta n_j} \varphi_1(\vec{r}_j) - \frac{\partial G_1(\vec{r}_2, \vec{r}_j)}{\partial x \delta n_j} \frac{\partial \varphi_1(\vec{r}_j)}{\partial n_j} \right] \, ds_j.
$$

Similarly, the time–averaged radiative power can be evaluated by calculating the complex Poynting vector flux through an imaginary cylinder of length $L$ and radius $\rho_0$ that encloses the system (see Figure 1)

$$
P_t = \frac{\rho_0 L c^2}{8\pi \omega \varepsilon_1} \int_0^{2\pi} \text{Re} \left\{ -i \left[ \varphi_1(\rho_0, \phi) \right]^* \frac{\partial \varphi_1(\rho_0, \phi)}{\partial \rho} \right\} \, d\phi.
$$

In the far–field region the calculation of the scattered fields given by the first of the Eq. (9) can be greatly simplified using the asymptotic expansion of the Hankel function for large argument [49]. After some algebraic manipulation, we obtain

$$
\varphi_1(\vec{r}) = \pi k_0 k_1 \rho \sin(\phi - \alpha) \sqrt{\frac{2}{\pi k_1 \rho}} e^{ik_1 \rho - \frac{\pi}{2}} f_{ang}(\phi) + \frac{e^{i(k_1 \rho - \frac{\pi}{2})}}{\sqrt{8\pi k_1 \rho}} \sum_{j=2}^{3} F^{(j)}_{ang}(\phi),
$$

$$
\frac{\partial \varphi_1(\vec{r})}{\partial \rho} = ik_1 \varphi_1(\vec{r})
$$
where the angular factors are given by
\[ f_{\text{ang}}(\phi) = e^{-ik_1(\cos \phi x_1 + \sin \phi y_1)}, \]

\[ F_{\text{ang}}^{(j)}(\phi) = \int_{\partial \Omega_1(t)}^{\Omega_1(t)} [i k_1(-y_j'(t) \cos \phi + x_j'(t) \sin \phi) \varphi(r_j'(t))] \frac{\partial \varphi(r_j(t))}{\partial n_j} |dt. \]

\[ \gamma_s = \frac{1}{\Gamma_{\text{inc}}} = 1 + \frac{\varepsilon}{16\pi\varepsilon_0 \varepsilon_p} \int_0^{2\pi} |F_{\text{ang}}^{(2)}(\phi)|^2 + |F_{\text{ang}}^{(3)}(\phi)|^2 \]

\[ -8\pi p \sin(\phi - \alpha) k_0 \varepsilon_1 \text{Re} \{f_{\text{ang}}(\phi) F_{\text{ang}}^{(2)}(\phi)\}
\]

\[ + F_{\text{ang}}^{(3)}(\phi) * + 2 \text{Re} \{F_{\text{ang}}^{(2)}(\phi) F_{\text{ang}}^{(3)}(\phi) * \} \} d\phi. \]

It worth noting that by taking \( F_{\text{ang}}^{(3)} = 0 \) in Eq. 21 we obtain the power radiated by a system conformed by only one graphene wire close to a dipole emitter (single wire system).

3. Results

In this section we apply the formalism sketched in previous sections to calculate the normalized radiative \( \gamma_s = P_s / P_{\text{inc}} \) decay rate and the radiative quantum efficiency \( \eta = \gamma_s / \gamma \) that specify the fraction of energy emitted as radiation. We assume that the curvature radius of the wires is sufficiently large as to describe their optical properties as those of a wire characterized by the same surface conductivity as planar graphene.

Taking into account the description of experimental results by the zero–thickness interface model \[58\], we consider the graphene layer as an infinitesimally thin, local and isotropic two–sided layer with frequency–dependent surface conductivity \( \sigma(\omega) \) given by the Kubo formula \[40, 47\], which can be read as \( \sigma = \sigma^{\text{intra}} + \sigma^{\text{inter}} \), with the intraband and interband contributions being

\[ \sigma^{\text{intra}}(\omega) = \frac{2ie^2k_B T}{\hbar(\omega + i\gamma_c)} \ln \left[ 2\cosh(\mu_c / 2k_B T) \right], \]

\[ \sigma^{\text{inter}}(\omega) = \frac{e^2}{\hbar} \left[ \frac{1}{2} + \frac{1}{\pi} \arctan \left[ (\omega - 2\mu_c) / 2k_B T \right] - \frac{i}{2\pi} \ln \left[ \frac{(\omega + 2\mu_c)^2}{(\omega - 2\mu_c)^2 + (2k_B T)^2} \right] \right], \]

where \( \mu_c \) is the chemical potential (controlled with the help of a gate voltage), \( \gamma_c \) the carriers scattering rate, \( e \) the electron charge, \( k_B \) the Boltzmann constant and \( h \) the reduced Planck constant.

In all the examples the dielectric elliptical wires are non magnetic (\( \mu_2 = \mu_3 = 1 \)) and \( \varepsilon_2 = \varepsilon_3 = 3.9 \). The graphene parameters are \( T = 300K \) and \( \gamma_c = 0.1 \) meV.

3.1. Single wire system: Radiation properties of one emitter coupled to an elliptical graphene wire

Firstly, we use GSIM given by Eq. 11 to examine the elementary system of an emitter coupled to a graphene wire of elliptical cross section. In Figure 2 we plot the radiative decay rate \( \gamma_s \) and the quantum efficiency \( \eta \) for an emitter located on the \( \hat{x} \) axis at \( d = 0.1 \mu m \) from the corner of an elongated graphene wire whose length perimeter is equal to 3.14\( \mu m \) and with a major (along \( \hat{x} \) axis) to minor (along \( \hat{y} \) axis) semi–axes ratios \( a / b = 2 \). To illustrate the effects of varying the \( \alpha \) orientation angle, in Figure 2a and 2b, we have plotted these curves for \( \alpha = 0 \) (horizontal polarization) and for \( \alpha = 90^{\circ} \) (vertical polarization), respectively. The curves corresponding to the circular wire \( a = b \) of the same perimeter is given as a reference. We observe that, similar to the case of quasi–rectangular graphene wires \[44\], the break of the 90\(^{\circ}\) rotational symmetry introduce an anisotropy in the optical behavior. This anisotropy is evident for the dipolar plasmonic resonance which for the case of circular cross section occur near 0.17\( \mu m^{-1} \) and that is split into two peaks, one of them near 0.14\( \mu m^{-1} \) and the other near 0.205\( \mu m^{-1} \). The first peak corresponds to \( \alpha = 90^{\circ} \) while the second peak corresponds to \( \alpha = 0 \), as clearly indicated in Figure 2 by the fact that both resonances are decoupled for dipole moment orientations parallel to either of the ellipse’s axes and that the first (respectively second) peak is absent when the dipole moment direction is parallel to (respectively along) the major axis.

Another quantity strongly depending on the dipole moment orientation is the quantum efficiency \( \eta \). Figure 2b shows that \( \eta \) takes a value near 0.7 at the high plasmonic resonance frequency (\( \omega / c \approx 0.205 \mu m^{-1} \)), a value considerably greater than that corresponding to the circular case for which \( \eta \approx 0.4 \). On the contrary, Figure 2c shows an insignificant value, near 0.14, at the low plasmonic resonance frequency.

On the other hand, we observe a pronounced dip in the radiation efficiency curves above the resonance frequency for horizontal polarization (Figure 2h) and below the resonance frequency for vertical polarization (Figure 2c). As pointed out in \[50\], these dips result from the destructive interference between the source dipole and that induced in the graphene wire. The minimum value reached at dip positions are more or less pronounced depending on whether \( \alpha = 0 \) or \( \alpha = 90^{\circ} \), as clearly indicated in Figure 2 by the fact that the minimum, which in the case of \( a = b \) and for horizontal polarization occur at 0.19\( \mu m^{-1} \), is blue shifted to 0.231\( \mu m^{-1} \) in the case of \( a = 2b \) whereas Figure 2d shows that the spectral position of the minimum for vertical polarization reaches a value of approximately 0.124\( \mu m^{-1} \) regardless whether \( a = b \) or \( a = 2b \).
Graphene plasmonic antenna – graphene surface plasmon

Figure 2. Radiative decay rate and quantum efficiency, both as a function of frequency, of a graphene coated elliptical wire with a major to minor semi-axes ratio \( a/b = 2 \) (\( a \approx 0.65, b \approx 0.325 \)). Constitutive parameters \( \varepsilon_2 = 3.9, \mu_2 = 1 \) and \( \varepsilon_1 = \mu_1 = 1 \). The graphene parameters are \( \mu_c = 0.5\text{eV}, T = 300 \text{ K} \) and \( \gamma_c = 0.1\text{meV} \). The emitter is localized on the \( \hat{x} \) axis (major ellipse semi-axis) at a distance \( d = 0.1\mu\text{m} \) from the left corner of the ellipse. (a) Horizontally orientation, (b) vertically orientation. The light cyan curve corresponds to a graphene-coated circular wire (\( a = b = 0.5\mu\text{m} \)).

3.2. Dimer Micro–antenna: Radiation properties of a system composed by two graphene coated elliptical wires

Having studied the radiation properties of a single elliptical wire, we next explore the effects that the incorporation of another wire, to form a dimer antenna consisting of two identical elements, has on the emission and the radiation spectrum of a dipole emitter in the proximity of the antenna. In particular, we consider the emitter located at the gap center of the dimer micro–antenna (see Figure 1).

Figure 3 shows the normalized radiative decay rate \( \gamma_s \) for an emitter horizontally oriented, i.e. the dipole moment of the source is oriented along the line connecting both elements, for gap sizes (the gap between the two wire elements) \( 2d = 0.4\mu\text{m}, 0.2\mu\text{m} \) and \( 0.1\mu\text{m} \). On comparing Figures 3b–c, we observe that the high frequency dipolar maximum which in the single wire case occur at \( 0.205\mu\text{m}^{-1} \) is red shifted from \( 0.197\mu\text{m}^{-1} \) to \( 0.189\mu\text{m}^{-1} \) when the gap \( 2d \) is decreased from \( 0.4\mu\text{m} \) to \( 0.1\mu\text{m} \). A similar behavior was found in case of metallic nano–antennas where the dipolar plasmonic resonance of the dimer structure is shifted to longer wavelengths as the gap between the two elements is decreased [15, 41]. Figure 3 also shows that the maximum value in the \( \gamma_s \) curve at the dipolar resonance is increased when the gap \( 2d \) is decreased. Moreover, the quantum efficiency \( \eta \) at the resonant frequency which in the single wire case is approximately \( 0.7 \), reach values slightly higher than \( 0.8 \) for a dimer graphene wire antenna. In particular, the calculated values in Figure 3 are \( \eta = 0.82, 0.836 \) and \( 0.847 \) for \( 2d = 4\mu\text{m}, 2\mu\text{m}, \) and \( 1\mu\text{m} \) respectively.

On the other hand, the non-radiating effect resulting from the destructive interference between the emitter and the antenna is becoming less noticeable as the gap decreases, as clearly indicated in Figure 3 by the fact that the minimum in the \( \gamma_s \) curve reaches a
Figure 4. Radiative decay rate and quantum efficiency of a micro-antenna composed by two graphene coated elliptical wires \((a/b = 2, a = 0.325\)). The emitter is localized on the \(\hat{x}\) axis (major ellipse semi-axis) at the center of the gap and the orientation angle \(\alpha = 90^\circ\) (vertical orientation). Gap size \(2d = 0.4\mu m\) (a), \(2d = 0.2\mu m\) (b) and \(2d = 0.1\mu m\) (c). The other parameters as the same as in Figure 2.

In Figure 4 we plot the normalized radiative decay rate \(\gamma_s\) for an emitter vertically oriented, i.e., with its dipole moment perpendicular to the connection line of both wires, for the same gap size values as in Figure 3. Unlike the horizontally orientation case in which the spectral position of the resonance peak is rather dependent on the gap size, in Figure 4 we see that the frequency at which the low frequency dipolar maximum occur almost does not shows any dependence on the gap size. We also see that the quantum efficiency \(\eta\) at the resonance frequency reaches values close to 0.3, a negligible value when it is compared with the values of \(\eta\) obtained in the horizontally orientation case.

An interesting result obtained in the vertical orientation is the strong reduction of the radiation decay rate at frequencies where non-radiating states occur, as clearly indicated in Figure 3 by the fact that the low frequency minimum in the \(\gamma_s\) curve is more pronounced as the gap size is decreased. For instance, \(\gamma_s\) takes a minimum value \(\approx 5 \times 10^{-5}\) for a gap size \(2d = 4\mu m\) (Figure 3a), a value \(\approx 2 \times 10^{-6}\) for \(2d = 2\mu m\) (Figure 3b) and a value \(\approx 10^{-7}\) for \(2d = 1\mu m\) (this last does not shown in Figure 3).

Moreover, on comparing Figures 3a–c we see that the minimum position is red shifted as the gap size is decreased. This behavior can be understood by taking into account that in the single wire case the spectral position of the non-radiating states are red shifted as the distance between the emitter, vertically oriented, and the wire is decreased [50].

To evaluate the dependence of the radiation properties with the location of the emitter, in Figure 4 we plot the radiation decay rate \(\gamma_s\) and the quantum efficiency \(\eta\) for an emitter as it moves away from the gap center of the micro-antenna (gap size \(2d = 1\mu m\)). Since the quantum efficiency for vertically polarization is low, we only exemplify the case of horizontal polarization for which the achieved efficiency is \(\approx 80\%\). The emission frequency is chosen as the high dipolar

Figure 5. Radiative decay rate and quantum efficiency as a function of the emitter location for the dipole resonance frequency. In (a) the dipole trajectory is along the \(\hat{y}\) axis (see inset), and in (b) the dipole trajectory is along the \(\hat{x}\) axis (see inset). The dipole moment is oriented along \(\hat{x}\) axis (horizontal orientation) and the dimer gap size is \(2d = 0.1\mu m\). All other the parameters are the same as in Figure 2.
plasmonic resonance $\omega/c = 0.18934\mu m^{-1}$ in Figure 8.

Firstly, the emitter is displaced vertically from the gap center as indicated in the inset in Figure 5a. We observe that the decay rate curve strongly decreases from its maximum value at the gap center to its minimum value from which the curve increases leading to an oscillatory behavior whose period $\approx \lambda/2 = \pi/(\omega/c) = 16.5\mu m$. This oscillatory behavior which occur for $y > 5\mu m$ also found in case of metallic dimer nano–antennas [41]. To appreciate the details at locations near the micro–antenna, in the inset of Figure 5a we have enlarged the horizontal scale, where it is clearly shown that a pronounced minimum is reached at a position slightly higher that the end of the elliptical wire composing the micro–antenna. In addition, the quantum efficiency takes a value $\approx 0.8$ for $y$ values that are lower than $5\mu m$ except in the neighborhood of $y = 0.43\mu m$ where the $\eta$ curve reaches a minimum value $\approx 3 \times 10^{-2}$. For $y > 5\mu m$, this curve presents the same oscillatory behavior as the $\gamma_s$ curve.

We next consider that the emitter, with horizontal orientation, is displaced horizontally from the position placed at $x = 0, y = 0.4\mu m$, as is indicated in the inset of Figure 5b. We see that the radiative decay rate decreases from the maximum value, $\approx 10$, at the gap center to a sharp minimum at approximately the position of the ellipse corner facing the gap (inset in Figure 5b). Next, the $\gamma_s$ curve increases reaching a maximum value at the center of the elliptical wire and then it decreases to another sharp minimum at the position of the far ellipse corner. On the other hand, the quantum efficiency takes a value $\approx 0.8$ reaching sharp minima values coinciding with that of the decay radiative curve. For $x$ values larger than $15\mu m$ both the radiative decay rate and the quantum efficiency take a value close to unity, suggesting that the emitter is uncoupled from the micro–antenna.

In Figure 6a we plot the spatial distribution of the scattered near electric field for an emitter polarized along the $\hat{x}$ axis ($\alpha = 0$) and placed at the gap center of the micro–antenna ($2d = 1\mu m$). The chosen emission frequency corresponds to the high dipolar resonance $\omega/c = 0.189\mu m^{-1}$. We can see a strongly enhancement of the field in the gap region and, to a lesser extent, around each wire. We have obtained a similar spatial field distribution for an emitter polarized along the $\hat{y}$ axis (not shown in Figure 6) but with a field enhancement that is near one order of magnitude less than the corresponding to the horizontal polarization. The strongly confinement of the field in the gap region, where the emitter is located, is responsible of the emitted power enhancement observed in Figures 3 and 4: at a frequency $\omega/c = 0.189\mu m^{-1}$ and $\omega/c = 0.142\mu m^{-1}$ respectively. However, the two configurations noticeably differ in the far field emission, as can be seen in Figure 6b where we have plotted the far field intensity as a function of the angle of radiation. We see that the far field intensity for the horizontal polarization is markedly greater (near 50 times) than that corresponding to the vertical polarization. This can be understood by taking into account that the quantum efficiency reach a value near to 0.85 for the horizontal polarization and a value near to 0.2 for the vertical polarization and that the field enhancement in the gap region for the horizontal polarization is near 10 times greater than that corresponding to the vertical polarization.

Finally, we investigate the tunability of the graphene micro–antenna by varying the chemical potential of the graphene sheets. We focused on the symmetric case where two wires are tuning at the same $\mu_e$. By increasing the chemical potential, we are able to tune the resonance frequency and we can define the sensitivity $s$ to the chemical potential as,

$$s = \frac{\partial \omega/c}{\partial \mu_e}. \tag{24}$$
Figure 7. Radiative decay rate and quantum efficiency as a function of frequency for different values of the chemical potential $\mu_c$, (a) $\mu_c = 0.5\text{eV}$, (b) $\mu_c = 0.75\text{eV}$, (c) $\mu_c = 1\text{eV}$. All other the parameters are the same as in Figure 3.

In Figure 7 we plotted the frequency dependence of the radiative decay rate and the quantum efficiency for $\mu_c = 0.5, 0.75,$ and $1\text{eV}$. The emitter is localized at the gap center and with its dipole moment along the $\hat{x}$ direction. On comparing Figures 7a–c, we observe that the dipolar resonance peak is blue shifted from $0.1893\mu\text{m}^{-1}$ to $0.2654\mu\text{m}^{-1}$ when the chemical potential $\mu_c$ is increased from $0.5\text{eV}$ to $1\text{eV}$. This fact can be understood by the fact that an increase in the chemical potential leads to an increase in the surface charge density on graphene sheets and, as a consequence, the plasmon resonance frequency increases. Figures 8a and b show the resonance frequency and the sensitivity $s$ as a function of the chemical potential $\mu_c$. The values of the resonance frequencies have been indirectly calculated estimating from the observation the positions of maxima of resonances in radiative decay rate curve spectra obtained for different values of $\mu_c$. We observe that the resonance frequency quadratically increases with the chemical potential. As a consequence, and as it can be seen in Figure 8b, the sensitivity $s$ linearly decreases with the chemical potential increase. Another interesting results is the increment of the quantum efficiency at the dipolar resonance frequency with the chemical potential. For example, $\eta \approx 0.84$ for $\mu_c = 0.5\text{eV}$ whereas $\eta$ reaches values $\approx 0.91$ and $\approx 0.94$ for $\mu_c = 0.75\text{eV}$ and $\mu = 1\text{eV}$, respectively.

Figure 8. Resonance frequency (a) and sensitivity $s$ (b) as a function of the chemical potential $\mu_c$ for the high dipolar resonance (the resonance corresponding to the horizontal polarization). All other the parameters are the same as in Figure 3.

4. Conclusions

The emission and radiation properties of a dipole emitter source close to a dimer graphene plasmonic antenna have been studied by applying an electromagnetically rigorous integral method based on the Green second identity. We considered the case of graphene-coated wires of elliptical section. In comparison with the circular section case, and as it might be expected on symmetry grounds, a frequency splitting of the dipolar plasmonic resonance is observed in the emission and radiation decay rate spectra. The high dipolar resonance (the resonance corresponding to the horizontal polarization) is red shifted as the gap size between the two wire components is decreases, whereas the spectral position of the low dipolar resonance (the resonance corresponding to the vertical polarization) is almost independent from the gap size value.

Our results shown similar values of the Purcell factor for both polarizations. For instance, the emission decay rate takes a value near $10^4$ for the horizontal polarization and a value near $10^3$ for the vertical polarization. However, the density of radiating states for horizontal polarization is larger than that corresponding to the vertical polarization, as indicated by calculated quantum efficiency values. For instance, the quantum efficiency is near 0.8 for horizontal polarization and near 0.3 for vertical polarization. This result means that a desirable antenna feature is achieved when the dipole moment of the emitter is
oriented along the line connecting both elliptic wires. Moreover, we have calculated the far field intensity which have served as a further test to confirm the previous guess.

Another interesting result revealed in this study is the fact that the quantum efficiency is strongly depending of the chemical potential of graphene coating. By increasing the chemical potential, the quantum efficiency is notably increased leading to an improve in the antenna performance.
