1. Introduction

Many important physical systems are characterized by complex actions, when formulated in terms of a path integral. But, if the action $S$ is not real, then $e^{-S}$ is not positive semi-definite and it cannot be interpreted as a probability distribution. In these cases, Monte Carlo calculations are not applicable directly. This is the so called sign problem. Many techniques have been proposed to overcome this problem, with important partial successes, but the sign problem is still unsolved for a variety of important physical systems and parameter values. In this context, any new idea that could improve our chances to simulate any of these models on larger lattices than are feasible today would be extremely valuable.

Recently, a new approach to control the sign problem was proposed in [1] and further developed in [2, 3, 4]. The approach consists in reformulating the quantum field theory (QFT) on a Lefschetz thimble [5, 1]. The Lefschetz thimble, associated with a saddle point $\phi$, is defined as the hypersurface formed by the union of all paths of steepest descent (SD) of the complex action ending in that saddle point $\phi$ at infinity. Both the Lefschetz thimble and the saddle point are constructed in an enlarged space obtained by complexifying each field component.

2. QFT on a Lefschetz thimble

In this section we briefly review the formulation of a quantum field on a Lefschetz thimble. Consider a QFT on a lattice (or any other system with a finite number of continuous degrees of freedom) defined by the action $S(\phi)$, where $\phi$ is a vector field whose number of components, $n$, is equal to the number of degrees of freedom in the system. Suppose that the initial field theory is defined for real fields, i.e, the expectation value of any observable $\mathcal{O}$ is given by,

$$\langle \mathcal{O} \rangle = \frac{\int_\mathcal{D} d\phi \mathcal{O}(\phi) e^{-S(\phi)}}{\int_\mathcal{D} d\phi e^{-S(\phi)}}$$

where $\mathcal{D}$ is the appropriate integration cycle for $S$ in the real domain $\mathbb{R}^n$. Now, consider $S$ in terms of the complexified fields, i.e, the field components $\phi_i$ are now allowed to be complex. Suppose, $S(\phi)$ is holomorphic in this complexified space and its critical points $\phi^\sigma$ given by

$$\frac{\partial S}{\partial \phi^\sigma} = 0$$

are non-degenerate,

$$\det \left[ \frac{\partial^2 S}{\partial \phi^\sigma \partial \phi^\tau} \right] \neq 0.$$  

Then, under suitable conditions on $S$ and $\mathcal{O}$ (typically fulfilled in physical systems) and for a generic choice of parameters, we have that [5, 15, 16]

$$\int_\mathcal{D} d\phi \mathcal{O}(\phi) e^{-S(\phi)} = \sum_\sigma m_\sigma \int_{\mathcal{J}_\sigma} d\phi \mathcal{O}(\phi) e^{-S(\phi)},$$

for some $m_\sigma \in \mathbb{Z}$. That is, an integral over the real domain $\mathcal{D}$ is equivalent to sum of integrals over the Lefschetz thimbles $\mathcal{J}_\sigma$. This result can be seen as a generalization of contour deformation in
one dimension. The Lefschetz thimbles $\mathcal{J}_\sigma$ associated with the critical points are many dimensional generalizations of the paths of steepest descent. The thimble $\mathcal{J}_\sigma$ is defined as the union of all paths governed by,

$$\frac{d\phi}{d\tau} = -\frac{\partial S}{\partial \phi}$$

(2.5)

and which end at the critical point $\phi^\sigma$ for $\tau \to \infty$. They are hypersurfaces of real dimension $n$ embedded in the complex manifold $\mathbb{C}^n$. Here, and later, the overhead bar represents complex conjugation. In this paper we will assume that $S$ is a Morse function, i.e., it has only non degenerate critical points.

On a Lefschetz thimble $\mathcal{J}_\sigma$, the imaginary part of the action $\Im S(\phi)$ remains constant. The measure term does introduce a new residual phase, due to the curvature of the thimble, but it is expected to be a smooth function of the fields (see later).

Eq. (2.4) represents an exact reformulation of the original path integral, but, for a QFT, reproducing the original integral exactly as in Eq. (2.4) is both impractical and unnecessary. In fact, for a large class of QFTs one can show that the regularization on a (suitably chosen) single thimble defines a QFT with the same degrees of freedom, the same symmetries (and symmetry-representations), the same perturbative expansion and the same naive continuum limit as the traditional formulation. On the basis of universality, these are the properties that justify a legitimate regularization of that QFT, and the formulation on a single thimble is expected to coincide with the traditional formulation, after suitable renormalization and in the continuum limit. (The same argument can be applied also to statistical models, at least in the vicinity of critical points.)

This leads to the formulation on a single thimble $\mathcal{J}_0$ as:

$$\langle \mathcal{O}(\phi) \rangle = \frac{\int_{\mathcal{J}_0} d\phi \mathcal{O}(\phi) e^{-S(\phi)}}{\int_{\mathcal{J}_0} d\phi e^{-S(\phi)}}$$

(2.6)

Note that universality is not a theorem (beyond perturbation theory), but it is nevertheless a property that one needs to assume anyway when studying any QFT on the lattice. So, this approach does not require new assumptions. It might certainly be that our present understanding of universality is incomplete, and the properties listed above do not define a QFT, not even in the continuum limit. But the thimble approach offers a well defined setup to investigate also this very fundamental question, by comparing the results obtained on different thimbles (although reproducing precisely that combination of thimbles that corresponds exactly to the traditional formulation seems not feasible).

Ref. [1] put forward another argument to justify the formulation on a single thimble (see also [5]). In fact, it is often possible to identify a single stationary point such that the contribution of the thimble attached to it is dominant, in the sense that the contribution of the other thimbles is either

---

1 Degenerate minima, as they typically occur in the presence of symmetries, can be either lifted or treated as discussed in [1].

2 In [1] this was shown explicitly only for QCD and for a self-interacting complex scalar field, but the arguments are much more general.

3 It would be also desirable to understand the role of reflection positivity in this setup. This is not easy, because even in the ordinary formulation naive reflection positivity does not hold, and it is not clear how it should be reformulated. Hopefully the analysis started in [6, 7] will shed some light on this issue.
Quantum field theory on a Lefschetz thimble

L. Scorzato

zero or exponentially suppressed, in presence of a large number of degrees of freedom. This may happen either because the system has a single global minimum, which is also a stationary point of the complexified action, or because there are degenerate global minima, that are however connected by symmetries, or because there are degenerate global minima with vanishing probability of tunneling. (When the global minimum is not a stationary point of the complexified action, it is always easy to locate the stationary point whose thimble contains the global minimum. This is typically the dominant one."

Note that this latter argument is not conclusive: it is possible, e.g., that a large number of stationary points may still accumulate near the global minimum giving a finite contribution. But, if universality is correct, these other contributions should either be equivalent, or they should represent lattice artifacts, that are effectively removed by the renormalization procedure.

There is certainly a deep connection between the Lefschetz thimble and the complex Langevin approaches. At the very least, because both share the same stationary points, although the relevant phase spaces are very different. The advantage of our approach is that a Monte Carlo on a thimble provably simulates a well defined functional integral, which, in turns, is related to the usual formulation on the basis of standard assumptions. We refer to [9, 10, 11, 12, 13, 14] for further insight in this topic.

Different numerical approach can be envisaged to perform the integration on the Lefschetz thimble. In the following we present the results obtained testing two of them: for the $U(1)$ one-link model we apply a Metropolis algorithm while for the relativistic Bose gas we use the Langevin dynamics. Details on the implementation of the two methods are presented in [2, 3]. (See [4] for another possible algorithm.)

3. One-plaquette model with $U(1)$ symmetry

As a first simple application of the method we now discuss a system with one degree of freedom, viz. the one-plaquette model with $U(1)$ symmetry. The action is given in terms of the gauge link $U = e^{i\phi}$ as

$$S = -i\frac{\beta}{2}(U + U^{-1}) = -i\beta \cos \phi.$$  \hspace{1cm} (3.1)

where $\phi$ in this case is a one component field. For real $\beta$ the action is complex, similar to real time gauge theories.

For this simple model, all the integrals can be evaluated analytically, which offers the chance to compare every detail of our numerical results to exact results. In particular the plaquette average of the phase $e^{i\phi}$ is given by,

$$\langle e^{i\phi} \rangle = \frac{J_1(\beta)}{J_0(\beta)}.$$  \hspace{1cm} (3.2)

with $J_n(\beta)$ being Bessel functions of the first kind. This analytic result offers the chance of a clear test of our algorithm.

Obtaining this result using stochastic methods is quite non-trivial. For example the complex Langevin method without ad-hoc optimizations gives the wrong result for this model [17].

In order to apply our method, we treat the field $\phi$ as complex. The action $S$ has two critical points at $\phi = 0$ and $\pi$. By explicitly constructing the Hessian, it is easy to show that both the
critical points are non-degenerate. In this simple model we can also compute the intersection numbers \( m_\sigma \), which turn out to be equal to 1 for both thimbles. The field configurations on the two thimbles are related by the discrete symmetry transformation \( \phi \rightarrow \pi - \phi \), and expectation values of observables can be written in terms of integrals over one thimble only.

For this model, one can explicitly derive the expression for the thimbles attached to the two saddle points. In the left panel of Fig. 1 we show that the fields obtained using the numerical method described above reproduce well the exact thimble.

We see systematic improvement in our results on increasing \( N_\epsilon = \epsilon^{-1} \), which represent the discretization parameter in our Metropolis algorithm (the continuum limit is given by \( \epsilon \rightarrow 0 \). With increasing \( N_\epsilon \) the sampled field configurations uniformly converge on the true thimble. In contrast, the flat Gaussian thimble \((N_\epsilon = 1)\) approximates the thimble quite well near the saddle point, but it noticeably different further away from the saddle point.

In the right panel of Fig. 1 we show the results for the expectation value of the observable \( e^{i\phi} \) for different \( \beta \). Again, the results from our method systematically approach the exact analytical result with increasing \( N_\epsilon \). For \( N_\epsilon = 200 \), the results from our method are identical (within statistical errors) to the analytical results for the range of \( \beta \) considered. In contrast, we notice that there is a large difference between the analytical result and those from Monte Carlo if the field configurations are sampled from the flat Gaussian thimble.

Finally, we discuss the residual phase in the context of the \( U(1) \) one-plaquette model. The question of the residual phase is an important one. We expect it to produce a milder sign problem (if at all), than the original sign problem. Nevertheless, it should be included in any quantitative estimate. In our formulation the full (complex) measure of integration is given by \( \det \left[J^\phi_{\eta}\right] e^{-S} \). The full integrals on the Lefschetz thimble are always real. This means that \( \sin \left(\arg \left(\det \left[J^\phi_{\eta}\right] e^{-S}\right)\right) \) does not contribute to the integral. The statement that the sign problem in our method is mild (or absent) means that \( \cos \left(\arg \left(\det \left[J^\phi_{\eta}\right] e^{-S}\right)\right) \) (residual phase) will vary very little (or not at all), in the region where \( |\det \left[J^\phi_{\eta}\right] e^{-S}| \) (probability measure) is significant.

For the \( U(1) \) one-plaquette model, the Jacobian of the transformation on each thimble is a
single number and is simply given by,

$$ f^\phi_\eta = \frac{-i\beta \sin \phi}{\eta}. $$

(3.3)

In Fig. 2 we show the residual phase vs the positive probability measure for this model. We see that the residual phase changes by very little for variations of the probability measure spanning many orders of magnitude. Moreover, the fluctuations of the residual phase grow milder as the true thimble is approached starting from the Gaussian thimble. Most importantly, the residual phase keeps the same sign throughout the full domain of integration, i.e., there is no sign problem for our method for this particular model.

4. Relativistic Bose gas at finite chemical potential

The model is defined by the following continuum action:

$$ S = \int d^4x [\mid \partial \phi \mid^2 + (m^2 - \mu^2)\mid \phi \mid^2 + \mu j_0 + \lambda \mid \phi \mid^4], $$

(4.1)

where $\phi(x)$ is a complex scalar field, $j_\nu := \phi^* \partial_\nu \phi - \phi \partial_\nu \phi^*$ and $\mu$ is the chemical potential. In this model (as in QCD) the density $\langle n \rangle = \frac{1}{V} \partial \ln Z / \partial \mu$ is expected to be zero up to a critical point. But, this phase transition is hidden in the standard Monte Carlo method because of the strong sign problem which appears as soon as $\mu \neq 0$.

To formulate and simulate the relativistic Bose gas on a Lefschetz thimble [1], we need to discretize the system defined by Eq. (4.1) and extend the action $S$ holomorphically. This is done by complexifying both the real and imaginary part of the original complex fields $\phi_a = \frac{1}{\sqrt{2}}(\phi_{1,a} + i\phi_{2,a})$, as $\phi_{a,x} = \phi^{(R)}_{a,x} + i\phi^{(I)}_{a,x}$, $a = 1, 2$, which leads to the action in $d$ dimensions [18]:

$$ S[\{\phi_{a,x}\}] = \sum_x \left[ \left( d + \frac{m^2}{2} \right) \sum_a \phi_{a,x}^2 + \frac{\lambda}{4} (\sum_a \phi_{a,x}^2)^2 - \sum_{a,v=1}^{d-1} \phi_{a,x} \phi_{a,x+v} + \sum_{a,b} i \sinh \mu \epsilon_{ab} \phi_{a,x} \phi_{b,x+0} - \cosh \mu \delta_{a,b} \phi_{a,x} \phi_{b,x+0} \right], $$

(4.2)
Quantum field theory on a Lefschetz thimble
L. Scorzato

(ε is the 2 dimensional anti-symmetric Levi-Civita symbol). The observables are defined as:
\[ \langle O \rangle_0 = \frac{1}{Z_0} \int_{\mathcal{J}_0} \prod_{a,x} d\phi_{a,x} e^{-S(\phi)} O(\phi), \]
\[ Z_0 = \int_{\mathcal{J}_0} \prod_{a,x} d\phi_{a,x} e^{-S(\phi)}, \]
where the integration domain \( \mathcal{J}_0 \) is the Lefschetz thimble \([16, 5]\) attached to \( \phi_{\text{glob}} \). The configuration \( \phi_{\text{glob}} \) is the global minimum of the real part of the action \( S_R = \Re \{ S \} \), when restricted to the original domain \( \mathbb{R}^{2V} \). More precisely, \( \mathcal{J}_0 \) is the manifold of real dimension \( N = 2V \), defined as union of all the curves of SD for \( S_R \), i.e., the curves that are solutions of Eq. 2.5 and that end in \( \phi_{\text{glob}} \) for \( \tau \to \infty \).

In presence of spontaneous symmetry breaking (SSB), the global minimum \( \phi_{\text{glob}} \) is degenerate. But, the whole procedure can be defined by introducing an explicit term of symmetry breaking:
\[ h \sum_{x,a} \phi_{a,x}, \]
where \( h \) is a real constant, that selects a specific minimum \([19]\) (that can be computed also analytically). Since \( h \) is real, the global minimum \( \phi_{\text{glob}} \) of \( S_R \) is also a stationary point of the imaginary part of the action \( S_I \), and hence the thimble is well defined. Physical results are obtained by extrapolating to \( h \to 0 \).

In this case we use the Langevin dynamics algorithm in order to move on the thimble, and in particular we restrict the simulation to the case of the flat Gaussian manifold \( \mathcal{G}_0 \) which in this case is a good approximation of the exact thimble (see [1, 19] for details) The results obtained in this way agree perfectly (within the rather small errors) with the results obtained with the algorithm of [20] and [21]. In particular, they show the correct scaling with the volume.

We report the results of simulations for the relativistic Bose gas in \( 3 + 1 \) dimensions (\( d = 4 \)). The mass and coupling were fixed at \( m = 1 = \lambda \), and \( \mu \) was varied from 0 to 1.3. In Fig. 4 we plot our results for the density \( \langle n \rangle \) and \( \langle |\phi|^2 \rangle \) in the most interesting range between \( \mu = 0.9 \) and \( \mu = 1.22 \). In these figures, we see a clear signal of the Silver Blaze phenomenon around \( \mu \sim 1.1 \). In all the simulations shown here we used \( \Delta t = 10^{-4} \), but we performed also some tests with \( \Delta t = 10^{-3} \) and \( \Delta t = 10^{-5} \) and we found no significant difference. The errorbars on each point are computed from the standard deviation of 10 to 20 independent histories, in order to take the autocorrelation effects into account. We used the sources \( h = 5 \times 10^{-3} \) and \( h = 10^{-3} \) to extract the limit \( h \to 0 \).

In Fig. 4 we plot the average phase for the same simulations reported above. The phase is used to reweight the observables. However, such reweighting brings corrections to the observables that are unnoticeable, within the statistical errors. As expected, the sign problem in \( \mathcal{G}_0 \) gradually increases on larger volumes and moving closer to the thimble will be eventually necessary.

Recently, a simulation on the exact thimble was carried out which verified our results and also showed that there is no sign problem coming from the residual phase in this case [4].

5. Conclusions

We have reported on the status of the Lefschetz thimble approach to the sign problem of QFTs. In particular, we have reviewed the justification of the approach, and we have summarized its application to two different simple models, in which we have employed two different algorithms.

\footnote{We thank Gert Aarts, Christof Gattringer and Thomas Kloiber for sharing their partially unpublished results with us.}
Quantum field theory on a Lefschetz thimble

L. Scorzato

Figure 3: Average density \( \langle n \rangle \) (left) and \( \langle |\phi|^2 \rangle \) (right) in the critical region for the lattices \( V = 4^4, 6^4, 8^4 \).

Figure 4: The data on the top-right show the average phase obtained with the Aurora algorithm on lattices \( 4^4, 6^4 \) and \( 8^4 \). It is interesting that the average phase is large precisely in the most interesting region just above \( \mu = 1 \). The dashed lines on the bottom-left display, for comparison, the average phase obtained with a naive phase-quenched Monte Carlo algorithm on lattices \( 4^4 \) and \( 6^4 \). Even on a \( 4^4 \) lattice, the sign problem in the phase-quenched algorithm, completely hides the interesting region.
The results are very encouraging and much work is currently ongoing to design better algorithms and apply these ideas to more QFTs.

Acknowledgments

We would like to thank Giovanni Eruzzi, Christian Torrero and Christian Schmidt for useful discussions. LS and FDR acknowledge support from the INFN - SUMA, the EU STRONGnet and the INFN QCDLAT projects.
