Circulating argonaute-bound microRNA-126 reports vascular dysfunction and treatment response in acute and chronic kidney disease

**HIGHLIGHTS**

New biomarkers are needed that report vascular function in patients with kidney disease

The endothelial microRNA, miR-126, was reduced with vascular inflammation (vasculitis)

miR-126 correlated with vascular health in chronic kidney disease

Circulating miR-126 may be a marker of vascular dysfunction

SUMMARY
Vascular and kidney dysfunction commonly co-exist. There is a need for biomarkers of vascular health. Circulating microRNAs are biomarkers; miR-126 is endothelial cell-enriched. We measured circulating miR-126 in rats with nephrotoxic nephritis (NTN) and humans with acute endothelial and renal injury (vasculitis associated with autoantibodies to neutrophil cytoplasm antigens (ANCAs)). We compared these findings to those from patients with chronic kidney disease (CKD) and end-stage renal disease (ESRD) and explored the relationship between miR-126 and vascular dysfunction. In NTN, miR-126 was reduced. In ANCA vasculitis (N = 70), pre-treatment miR-126 was reduced compared to health (N = 60) (88-fold). miR-126 increased 3.4-fold post-treatment but remained lower than in health (~26-fold). Argonaute 2-bound miR-126 increased with ANCA vasculitis treatment. miR-126 did not differ between CKD (N = 30) and health but its concentration correlated with endothelial dysfunction. miR-126 was reduced in ESRD (N = 15) (~350 fold). miR-126 may be a marker of vascular inflammation and could aid decision-making.

INTRODUCTION
Vascular dysfunction commonly co-exists with kidney disease and contributes to an increased risk of cardiovascular disease (CVD). A severe, acute form of this vascular-renal phenotype is seen in patients presenting with anti-neutrophil cytoplasm antibody-associated vasculitis (AAV), a rare autoimmune disorder. The most frequent severe manifestations of AAV involve endothelial injury giving rise to a rapidly progressive glomerulonephritis and pulmonary hemorrhage. Despite current treatments overall survival remains poor (Flossmann et al., 2011; Hoffman et al., 1992) with many patients suffering chronic inflammation, a major contributor to the development and progression of both CVD (Hahn, 2003) and chronic kidney disease (CKD) (Landray et al., 2004). Furthermore, those who respond to treatment remain at risk of further disease relapses (Boomsma et al., 2000).

Identifying AAV early and assessing its response to treatment remain important clinical challenges. In those with renal involvement, the measurement of renal function using serum creatinine is often inadequate because substantial renal damage can occur before function is impaired to a detectable extent (Hewitt et al., 2004). Additionally, although serum creatinine may fall with treatment, it remains unclear whether histological inflammation continues once renal function has stabilized. Also, currently, there are no good measures of disease activity in those with extra-renal AAV alone. Biomarkers specific to small vessel inflammation would not only allow early implementation of appropriate treatments but also help identify those patients with grumbling disease activity and potentially predict disease relapses (Kitching et al., 2020).

While AAV might be considered a phenotypic extreme, patients with CKD due to any cause are at an increased risk of CVD (Foley et al., 1998). Indeed, those with CKD have a substantially higher chance of dying from CVD than of progressing to end-stage renal disease (ESRD) (Sarnak et al., 2003). Increased arterial stiffness, a marker of CVD risk (Blacher et al., 1999; Guerin et al., 2008), is a commonly recognized feature of CKD (Guerin et al., 2008), and an independent predictor of mortality and survival in these patients.
The endothelium is an important regulator of arterial stiffness (Wilkinson et al., 2004), and endothelial dysfunction is also a common feature of CKD (Endemann and Schiffrin, 2004; van Guldener et al., 1997, 1998) and a predictor of CVD (Perticone et al., 2001).

MicroRNAs (miRs) are small (~22 nucleotide-long) non-protein coding RNA species involved in post-transcriptional gene product regulation (Bartel, 2009). In blood, miRs are reported to be stable being protected from degradation by extra-cellular vesicles (such as exosomes), RNA binding protein complexes (such as argonaute 2 – Ago2) and lipoproteins (Mitchell et al., 2008; Zhou et al., 2013). As miRs are amplifiable and some are tissue restricted, they represent a new reservoir for biomarker discovery. For example, miR-122 is an established biomarker for liver injury (Starkey Lewis et al., 2011).

miR-126 is enriched in endothelial cells and is a regulator of vascular integrity and angiogenesis. The -3p and -5p forms of miR-126 have activity in endothelial cells – 3p is anti-inflammatory (Harris et al., 2008) and 5p is pro-proliferative (Schober et al., 2014). miR-126 is reported to be released from endothelial cells bound to Ago2 and in extra-cellular vesicles, which can transfer functional miR-126 into recipient cells to promote vascular repair (Zhou et al., 2013). When endothelial cells were stimulated with the pro-inflammatory cytokine TNFα, the miR-126 cargo of their extra-cellular vesicles was reduced by 80%, consistent with vesicular miR-126 reporting endothelial inflammation (Alexy et al., 2014). Reduced levels of circulating miR-126 have been described as a potential biomarker for vascular disorders such as diabetes (Jansen et al., 2013; Zampetaki et al., 2010) and myocardial infarction (Zampetaki et al., 2012). In patients with CKD, miR-126 has been reported to fall with worsening renal function (Fourdinier et al., 2019). miR-126 is also expressed in platelets (Kaudewitz et al., 2016) and its circulating level has been reported to reflect the circulating platelet count and activation state (Lorenzen et al., 2012; Willeit et al., 2013).

We hypothesized that circulating miR-126 would report vascular dysfunction in patients with kidney disease. As ‘proof-of-concept’, we first measured miR-126 in a relevant animal model, then in those with AAV. Finally, we measured miR-126 in patients with CKD and ESRD, as well as explored the relationship with established measures of endothelial function.

RESULTS
Circulating miR in NTN model
In NTN rats, plasma miR-126 was reduced compared with untreated controls when the data were normalized by miR-1287 (Figure 1). This reduction in miR-126 was also reported by raw Ct values without any normalization (control Ct 27.6 [27.0–27.8], n = 6, NTN Ct 29.3 [28.4–30.1], n = 5, p = 0.02) There were no differences in miR-122 or miR-125a between NTN and controls (Figure 1).

Effect of blood processing
In healthy subjects, there was a significant difference in miR-126 concentration between plasma and serum. There was a significant decrease in miR-126 after blood storage for 24hr at both room temperature and at 4°C (Figure S1A). After 7d delay in processing, the concentration of miR-126 significantly increased relative to 24hr. Hemolysis accompanied this increase in miR-126 (for serum, no delay: A414 0.22 [0.20–0.31]; 7d delay: A414 1.80 [0.60–1.80], p = 0.03; for plasma, no delay: A214 0.16 [0.16–0.28]; 7d delay: A214 0.30 [0.22–0.45]; p = 0.03). Based on these data, only immediately processed plasma samples were used in all
subsequent studies. After processing human blood into plasma or serum, storage at room temperature or
4°C for 24 hr or 7 days had no statistically significant effect on miR-126 concentration (Figure S1B). There-
fore, after immediate isolation of plasma from blood, samples could be stored for short periods before
analysis.

Circulating miR in AAV
Seventy patients with AAV were recruited into this study. Pre- and post-treatment clinical data are shown in
Table 1. No patients had diabetes or received anti-platelet treatment. Pre-treatment, the plasma miR-126
concentration was 88-fold lower than in healthy controls (AAV median 0.8 fM [IQR 0.3–2.9], healthy subjects
70.4 fM (17.2–770) (Figure 2). ROC analysis was performed to quantify the accuracy of miR-126 with regard
to distinguishing health from AAV. The area under the curve was 0.87 (95% CI: 0.80–0.94). At a cutoff of
>33 fM, specificity was 96% (95% CI: 88–99) and sensitivity was 69% (57–80). Post-treatment, all 70 patients
achieved disease remission (Table 1). Plasma miR-126 concentration increased 3.4-fold from pre-treatment
levels (post-treatment median 2.7 fM [IQR 0.5–9.8]) but did not return to healthy levels. miR-122 plasma
concentrations were not different between pre- and post-treatment samples from patients with AAV
(pre-treatment 1.6 fM [0.7–3.4], post-treatment 1.8 fM [0.7–4.7]). There was no correlation between miR-
126 and the patient’s platelet count either pre- or post-treatment (Figure S2A).

Urine miR-126 was measured pre- and post-immunosuppressive treatment (Figure 3). Using 3 different
normalization methods (spike-in microRNA, urinary creatinine or internal microRNA) the urinary concentra-
tion of miR-126 consistently decreased post-treatment.

Mechanism of miR-126 release into the circulation
miRs circulate bound to proteins or encapsulated in extra-cellular vesicles such as exosomes. Plasma from
healthy volunteers was fractionated by differential centrifugation and extra-cellular vesicles were isolated
(confirmed by nanoparticle tracking analysis – Figure 4A). miR-126 was enriched in the ‘protein fraction’ as
opposed to the extra-cellular vesicle fraction (29-fold increase in supernatant compared to pellet) (Fig-
ure 4B). The RNA binding protein Ago2 was isolated from plasma and the bound miR-126 concentration
measured. There was a significant increase in Ago2-bound miR-126 in those with AAV post-treatment.

Table 1. Clinical data for patients with AAV pre- and post-treatment

| Characteristics          | Pre-treatment (n = 70) | Post-treatment (n = 70) | p value |
|--------------------------|-----------------------|------------------------|---------|
| Age, years               | 62 ± 14 (27–82)       | –                      | –       |
| Sex, M/F                 | 43/27                 | –                      | –       |
| Organs involved          | 2 ± 1 (1–6)           | –                      | –       |
| Kidney                   | 44                    | –                      | –       |
| Lung                     | 33                    | –                      | –       |

| Nerve                    | 13                    | –                      | –       |
| Eyes                     | 9                     | –                      | –       |
| eGFR, mL/min/1.73m²      | 46 ± 34 (4–124)       | 57 ± 29 (9–121)        | 0.04    |
| Creatinine, μmol/L       | 200 ± 177 (54–962)    | 150 ± 144 (64–1000)    | 0.03    |
| ALT, U/L                 | 20 ± 15 (6–83)        | 20 ± 10 (4–48)         | 0.94    |
| ALP, U/L                 | 96 ± 62 (13–338)      | 67 ± 18 (39–122)       | <0.001  |
| GGT, U/L                 | 55 ± 44 (11–182)      | 33 ± 26 (10–148)       | <0.001  |
| Albumin, g/L             | 28 ± 7 (14–41)        | 37 ± 4 (24–46)         | <0.0001 |
| CRP, mg/L                | 82 ± 75 (3–275)       | 6 ± 15 (0–108)         | <0.0001 |
| Hemoglobin, g/L          | 107 ± 23 (62–157)     | 124 ± 28 (2–170)       | <0.0001 |
| Urine protein:creatinine | 141 ± 188 (0–948)     | 107 ± 146 (0–531)      | 0.82    |

The data are shown as mean ± SD with range. Significance of numerical data between groups was ascertained using a 2-
tailed paired t test.
Figure 4C, consistent with this miR biomarker being specifically bound to Ago2. By contrast there was no significant treatment-induced change in miR-126 in the extra-cellular vesicle fraction (Figure 4D). There was no increase in Ago2-bound miR-122 and no change in plasma Ago2 concentration with treatment (data not shown).

Circulating miR-126 in CKD
Having demonstrated proof-of-concept that miR-126 changes with acute endothelial/kidney injury, we explored its circulating concentration in CKD. This condition is associated with chronic endothelial dysfunction and high cardiovascular risk. There were no patients in this cohort with diabetes. Samples were analyzed from patients with CKD (n = 30) and hemodialysis-dependent ESRD (n = 15), immediately before and after dialysis (Table 2). In patients with ESRD, miR-126 was substantially reduced compared with healthy subjects and patients with CKD (352- and 358-fold, respectively). There was a modest increase following a hemodialysis session (4.7-fold) (Figure 2). There was a range of plasma miR concentrations in patients with CKD, which we hypothesized might reflect differences in vascular health across this patient group. For these patients, we correlated miR concentrations against a range of well-recognized measures of vascular function. miR-126 correlated significantly with PWV ($r^2 = 0.2$), circulating ADMA ($r^2 = 0.28$), ET-1 ($r^2 = 0.14$) and urate concentrations ($r^2 = 0.19$), as well as proteinuria ($r^2 = 0.17$) (Figure 5). miR-126 correlated weakly with serum creatinine ($r^2 = 0.12$). There was no relationship between miR-122 and any of the measures of vascular or renal function assessed. There was no correlation between miR-126 and the patient’s platelet count either in the CKD or ESRD groups (Figures S2B and S2C).

DISCUSSION
The current study develops the potential role of miR-126 as a circulating biomarker of vascular function in acute and CKD. We initially achieved proof of concept in rodents and then went on to study AAV as a prototype of severe, acute kidney injury and vascular dysfunction that is aggressively treated with immunosuppression. Then, we went on to study patients with CKD as they have a heavy burden of vascular dysfunction. In a clinically relevant rat model, a lower circulating miR-126 (but not other miR species) was associated with disease. We have demonstrated that in patients with AAV, circulating miR-126 concentrations are low at disease presentation and rise with successful treatment. Pre-treatment levels are lower than those seen in health and in CKD. Following treatment, miR-126 rises but not to levels seen in health. A liver-specific miR species (miR-122) showed no differences in patients with AAV before or after treatment. In patients with CKD, miR-126 correlated with other markers of vascular health. miR-126 was substantially reduced in patients with ESRD. Thus, miR-126 may be a useful marker of vascular inflammation and, with development, may help clinical decision-making.
miRs are an area of substantial research interest, in part because they represent potential disease biomarkers. It is widely believed that one of their key properties is that they are stable in the circulation (Mitchell et al., 2008). In the current study, we have demonstrated that for miR-126 this is not the case: significant degradation occurred if the sample was left unprocessed for 24 hr. We have reported similar instability for miR-122 (Lopez-Longarela et al., 2020). We also demonstrated that hemolysis may increase the concentration of miR-126 present in the sample. Furthermore, despite reports that miRs are detected at similar concentrations in plasma and serum, plasma miR-126 was substantially higher than serum. Therefore, we recommend the immediate processing of plasma samples in future studies of miR-126.

Therefore, we recommend the immediate processing of plasma samples in future studies of miR-126.

Figure 3. Urine miR-126 in patients with AAV, pre- (Pre-AAV) and post- (Post-AAV) treatment
Each point represents the 2^−ΔΔCT value (normalized by C. elegans miR-39 spike-in control (A), urinary creatinine concentration (B) and miR-671 (C)) of miR-126. Significance determined by Wilcoxon Test.

Figure 4. miR-126 is bound to argonaute 2 (Ago2) in human plasma
(A) size and number of particles measured by nanoparticle tracking analysis (NTA) following isolation of extra-cellular vesicles from human plasma by differential centrifugation.
(B) Dot plot of miR-126 measured in the extra-cellular vesicle containing pellet and supernatant after ultracentrifugation of human plasma.
(C) Dot plot of miR-126 measured in the antibody isolated Ago2 fraction from 8 patients with AAV before treatment (Pre-AAV) and after treatment (Post-AAV). The y axis represents copy number obtained from the Ago2 pull-down minus the copy number obtained from IgG control pull-down from the same sample.
(D) Dot plot of miR-126 measured in the extra-cellular vesicle containing pellet from 8 patients with AAV before treatment (Pre-AAV) and after treatment (Post-AAV). The horizontal line represents the median and the error bars represent the IQR. Significance determined by Wilcoxon Test.
miR-126 increased in the circulation following successful treatment of patients with AAV. There was no change in miR-122, a liver-specific miR not expressed in the endothelium. This is consistent with a specific change in the endothelium but deeper analysis of multiple miRs is required. In spot urine samples, miR-126 was reduced by treatment, which may contribute to the increase in the circulation. miR circulate encapsulated in extra-cellular vesicles such as exosomes and bound to proteins especially Ago2, but the relative contribution and biological importance of each fraction is controversial (Chevillet et al., 2014). In our study, when plasma was fractionated by centrifugation miR-126 predominately remained in the supernatant. This is consistent with studies that report a low amount of miR-126 in human exosomes (Chevillet et al., 2014). Importantly, we demonstrate here that miR-126 is bound to the circulating protein Ago2 and this fraction increases in patients with AAV following successful disease treatment. It is reported that stimulation of endothelial cells with TNF-α resulted in a decrease of miR-126 (Alexy et al., 2014). This is in keeping with our own findings and suggests that the reduction in circulating miR-126 in those with active AAV may reflect a degree of endothelial dysfunction secondary to inflammation. This hypothesis is further supported by miR-126 being enriched in the endothelium (Harris et al., 2008) and our strong correlation between the circulating miR-126 and markers of endothelial function such as pulse wave velocity and ADMA. From a clinical perspective, a circulating biomarker that reports vascular health could have widespread utility and prospective studies should qualify miR-126 in a range of settings, including other systemic inflammatory disorders such as rheumatoid arthritis and systemic lupus erythematosus.

In keeping with our hypothesis that miR-126 might act as a measure of vascular integrity, circulating levels did correlate with well-recognized measures of endothelial dysfunction in our CKD cohort namely, high PWV, ADMA, ET-1, and urate. Plasma ADMA, an endogenous inhibitor of nitric oxide synthase, and plasma ET-1 were measured as components of the nitric oxide and ET systems, respectively. Both contribute to vascular dysfunction in CKD and an imbalance (more ET-1/less nitric oxide) may contribute to vasoconstriction, inflammation and atherosclerosis (Boger, 2003; Dhaun et al., 2006). Serum urate has also emerged as an important risk factor for cardiovascular risk and CKD progression (Feig et al., 2008). Treatment of asymptomatic hyperuricemia has been shown to improve renal function (Kanbay et al., 2007) and delay disease progression (Siu et al., 2006) in patients with early CKD. From a clinical perspective, ET receptor antagonism is being investigated as a novel therapeutic strategy for renoprotection in CKD (Dhaun and Webb, 2019). It has been shown to not only lower proteinuria but also serum urate (Dhaun et al., 2013; Heerspink et al., 2019). Furthermore, given there is often reciprocal up-regulation of the nitric oxide system when the ET system is down-regulated (Dhaun et al., 2006) an ET blocking strategy may offset some of the potentially deleterious effects of elevated circulating ADMA.

Interestingly, our data suggest no substantial difference in circulating miR-126 between health and CKD. The lack of a clear difference may relate to the CKD population we studied as they had minimal comorbidity without overt CVD. Additionally, we excluded those with diabetes. Indeed, the “vascular health” of our CKD subjects is demonstrated by a mean pulse wave velocity of 6.8 m/s, significantly lower than that of 8.2 m/s for a group with a similar eGFR reported in a study by Wang et al. (Wang et al., 2005). They used a similar technique for measuring arterial stiffness but included patients with diabetes and CVD. Furthermore, our subjects were relatively young (~50 years), with good blood pressure control (~135/80 mmHg).

### Table 2. Clinical data obtained for CKD patients and ESRD patients pre-hemodialysis (HD)

| Characteristics | CKD (n = 30) | Pre-HD (n = 15) |
|-----------------|--------------|-----------------|
| Age, years      | 56 ± 16 (26–82) | 59 ± 12 (34–82) |
| Sex, M/F        | 21/9 | B/7 |
| eGFR, ml/min/1.73m² | 25 ± 14 (7–57) | – |
| Creatinine, µmol/L | 217 ± 133 (74–654) | – |
| ALT, U/L        | 19 ± 8 (9–50) | 15 ± 6 (7–25) |
| ALP, U/L        | 97 ± 38 (40–182) | 100 ± 43 (52–178) |
| CRP, mg/L       | 5 ± 2 (2–7) | 14 ± 21 (2–77) |
| Hemoglobin, g/L | 123 ± 16 (83–160) | 122 ± 12.51 (94–139) |

The data are shown as mean ± SD with range.

and reasonably preserved renal function (eGFR ~75 mL/min). Thus, future studies should extend to the wider spectrum of CKD.

With further clinical development, miR-126 may have utility as a biomarker of vascular dysfunction in patients with kidney disease (and possibly in people with normal kidney function). Such a miR biomarker may provide a readout of cardiovascular drug efficacy that translates from pre-clinical models into early phase clinical trials. In support of this, we have demonstrated that miR-126 tracks effective treatment in patients with AAV and reports injury when translated back into a rat model of nephrotoxic nephritis. The work presented here provides proof of concept data to build on in larger studies that test utility, both in the specific clinical scenario of reporting disease activity in vasculitis, and across a broader group of patients with acute kidney injury and CKD.

Limitations of the study

miR-126 is expressed in platelets and this represents an alternative source of miR-126 in the circulation. There was no correlation with the platelet counts across patient groups, but this does not exclude a difference in platelet activation state. While this cannot be excluded when comparing the AAV patients pre- and post-treatment it is unlikely to be a factor in the CKD group, where miR-126 correlated significantly with markers of endothelial dysfunction but not with platelet counts. Future studies could replicate our observations in platelet poor plasma as described by Sunderland et al. (Sunderland et al., 2017). We represent miR-126 in AAV as an absolute concentration generated from a standard curve using synthetic miR-126. The values generated allow comparison across groups, but the absolute value should be interpreted with caution as the reverse transcription efficiency may differ between synthetic target in buffer and plasma. Furthermore, release of miR-126 from platelets during sample processing could lead to higher apparent concentrations than are present in the cell-free fraction in vivo. Our data demonstrate that the Ago2 fraction of miR-126 changes with treatment of patients with AAV. To thoroughly characterize the role of extracellular vesicles, future studies should follow the guidelines published by the International Society of Extracellular Vesicles (Thery et al., 2018).

Supplementary figure 1: Effect of storage on serum & plasma miR-126. Related to figure 2.

A) Bar graphs displaying median Ct values of miR-126 measured by qPCR. Blood samples were collected from healthy volunteers (n=6). One serum and plasma blood tube was centrifuged and the supernatant frozen at -80°C without delay. The remaining blood tubes were left at room temperature (RT) or 4°C for 24h or 7 days before being processed and stored at -80°C. Error bars represent the interquartile range.

B) Serum and plasma samples were immediately centrifuged to isolate serum/plasma. One serum and one plasma sample were stored at -80°C without delay and the remaining tubes were left at room temperature (RT) or 4°C for 24h or 7 days. Error bars represent the interquartile range.
Supplementary figure 2: The relationship between plasma miR-126 and platelet count in patients with ANCA-associated vasculitis (AAV). Related to figure 2.
Pre and post treatment (A), chronic kidney disease (B) and End-stage kidney disease (C).
Supplementary figure 3: Standard curves used for absolute quantification of miRs. Related to Figure 2.

(A) miR-122 and (B) miR-126 standard curves for absolute quantification in patient samples. The solid blue line shows the semilog and the dotted line shows the 95% confidence interval (CI).
Transparent Methods

Participant groups

All studies were approved by the local research ethics committee and performed in accordance with the Declaration of Helsinki. The study, entitled “MicroRNA signatures of disease activity in ANCA-associated vasculitis”, REC reference 13/ES/0126 (formerly 10/S1402/33) was approved by The Tissue Governance committee in June 2015. Informed consent was obtained from all study participants.

Patients with ANCA Associated Vasculitis (AAV)

Patients presenting with AAV were recruited at the Royal Infirmary of Edinburgh, UK. Inclusion criteria were seropositivity for ANCA and organ-threatening disease requiring immunosuppression. Disease activity was graded according to the BVAS (scores range from 0 to 63, with higher scores indicating more active disease) (Mukhtyar et al., 2009) and by investigators’ assessments of disease activity as remission, ongoing active disease (treatment failure), or relapse. Remission was defined as a BVAS score of 0 that was maintained for 2 months and a prednisone dosage of ≤10 mg/day.

Patients with CKD

Subjects were recruited from the renal outpatient clinic at the Royal Infirmary of Edinburgh. The inclusion criteria were: male or female CKD patients, 18-65 years old and clinic BP ≤160/100 mmHg, whether or not on anti-hypertensive medication. We excluded patients with a renal transplant or on dialysis, patients with systemic vasculitis or connective tissue disease, those with a history of established cardiovascular disease, peripheral vascular disease, diabetes mellitus, respiratory disease, neurological disease, current alcohol abuse or pregnancy.
**Patients with ESRD**

Inclusion criteria were: age 18 or over, treated with haemodialysis (HD) for over 3 months. Patients affected by liver disease or with a history of hepato-biliary surgery were excluded; other exclusion criteria were consumption of cytochrome P450-inducing medications, past medical history of epilepsy, cancer, alcoholism and/or psychiatric disease. All patients were treated with HD for 4-5 hours per session, 3 times per week. Data collected included demographic characteristics, cause of ESRD, time on dialysis and current medications. As heparin in blood samples can inhibit polymerase chain reaction (PCR), blood samples were only used when the patient had not been exposed to heparin in the preceding 24 hours.

**Healthy subjects**

Adults with no medical complaints and no medication use were recruited and blood was drawn with informed consent.

**Blood samples**

In healthy subjects, blood was collected into 3 EDTA plasma (2.7 ml) and 3 serum (4.9 ml) tubes. One of each type of blood tube was processed without delay – by centrifugation at 1200 x g for 10 min at 4\(^\circ\)C and then supernatant then frozen at -80\(^\circ\)C. The remaining tubes of blood were left unprocessed at room temperature or 4\(^\circ\)C for 24h or 7 days. Hemolysis was quantified by spectrophotometric methods as described previously (Kirschner et al., 2013). In a second study plasma and serum was left at room temperature or 4\(^\circ\)C for 24h or 7 days.

In patients with AAV, blood samples were taken at study entry (before treatment) and at disease remission (as defined above). For CKD patients, samples were taken from a previously published study and were collected on the study day (Lilitkarntakul et al., 2011). Blood was collected into EDTA tubes and processed immediately as above. Urine was also collected and immediately frozen at -80\(^\circ\)C.
Plasma asymmetric dimethylarginine (ADMA), an endogenous inhibitor of nitric oxide synthesis, was measured using an optimised, fully validated high performance liquid chromatography method (intra- and inter-assay variations of 1.9% and 2.3%, respectively) (Blackwell et al., 2007). Plasma endothelin-1 (ET-1), the most potent endogenous vasoconstrictor, which contributes to CKD development and progression, (Dhaun et al., 2006) was determined by radioimmunoassay (Peninsular Laboratories Europe, St. Helens, UK) (assay variations 6.3% and 7.2%) (Strachan et al., 1999). The urate assay was based on the methods of Trivedi and Kabasakalian (Trivedi et al., 1978). Uric acid is oxidized to allantoin by uricase with the production of hydrogen peroxide (H$_2$O$_2$). The H$_2$O$_2$ reacts with 4-aminoantipyrine (4-AAP) and 2,4,6-tribromo-3-hydroxybenzoic acid (TBHB) in the presence of peroxidase to yield a quinoneimine dye. The resulting change in absorbance at 548 nm is proportional to the uric acid concentration in the sample. The limits of detection and quantification for the urate assay are 0.01 mmol/l and 0.015 mmol/l, respectively.

**Extra-cellular vesicle isolation**

Human plasma was fractionated by differential centrifugation to concentrate extra-cellular vesicles, as previously described (Chevillet et al., 2014). Plasma (1 mL) was centrifuged at 500 x g for 30 min then 12,000 x g for 20 min. The supernatant was then ultracentrifuged at 100,000 x g for 1h to pellet extra-cellular vesicles. The remaining supernatant is referred to as the 'protein fraction'. The vesicles were re-suspended and then pelleted a second time by ultracentrifugation. Extra-cellular vesicle presence and number was quantified by nanoparticle tracking analysis as previously described (Oosthuyzen et al., 2013). miR concentration in each fraction was determined by PCR, described below.

**Ago2 isolation**

MagnaBind goat anti-mouse IgG magnetic bead slurry, 100 μL, (Thermo Scientific, Waltham, USA) was incubated with 10 μg of mouse monoclonal anti-Ago2 (Abcam, Cambridge, UK) or mouse normal IgG (Santa Cruz Biotechnology, Dallas, US) antibodies for 2h at 4°C. The
antibody-coated beads were then added to plasma and incubated overnight at 4°C with rotation. Beads were washed and each sample then eluted in RNase free water before QIAzol was added for RNA isolation. Ago2 isolation was determined by Western blot analysis as described (Dear et al., 2011).

Measurement of arterial stiffness

In a subset of patients gold standard pulse wave velocity (PWV) was measured by the foot-to-foot wave velocity method using the SphygmoCor™ system (SphygmoCor™ Mx, AtCor Medical, Sydney, Australia, version 6.31), in which a high-fidelity micromanometer (SPC-301, Millar Instruments, Texas, USA) was used to determine carotid-femoral PWV (Oliver and Webb, 2003).

Measurement of plasma and urine miR

The following miR were measured: miR-126-3p, miR-122-5p, miR-1287 and miR-671.

RNA extraction

RNA was extracted from each sample (50 µl) using the miRNeasy serum/plasma kit (Qiagen, Venlo, Netherlands).

PCR

After RNA extraction, 5 µl of each eluate was reverse transcribed into cDNA using the miScript II RT Kit (Qiagen, Venlo, Netherlands). The synthesised cDNA was ten-fold diluted and used for cDNA template in combination with the miScript SYBR Green PCR Kit (Qiagen, Venlo, Netherlands) using the specific miScript assays (Qiagen, Venlo, Netherlands). Real-time PCR was performed on a Light Cycler 480 (Roche, Basel, Switzerland) using the recommended miScript cycling parameters.
**Absolute miRNA quantification**

Absolute quantification of miRs was achieved by generating a standard curve using synthetic target. Standard curves were generated by reverse transcribing known concentrations of miScript miRNA mimics (Qiagen, Venlo, The Netherlands) in 0.1X TE buffer spiked with 10 ng/μl Poly-C (Sigma-Aldrich, Gillingham, UK). The resulting cDNA was measured using serial dilutions on 3 different plates on three different days to demonstrate minimal variability (Supplementary Figure 3).

**Relative quantification**

MiR expression was analysed using the DCt method (Schmittgen and Livak, 2008). A C. elegans miR mimic was used as a spiked-in control (miR-39). This allowed for the Ct values for the miRs of interest to be normalised to the spiked-in control. The data obtained were translated by the $2^{-\Delta\Delta CT}$ method.

**Statistical analysis**

Data are presented as mean ± standard deviation for patient characteristics and as median and interquartile range (IQR) for all other datasets. Each dataset was analysed for normality using a Shapiro-Wilk test. For non-parametric datasets, comparisons were made using the Mann-Whitney test or Wilcoxon matched-pairs signed rank test. For the study of patients with ANCA vasculitis, with 70 patients the probability is 80% that the study will detect a pre- and post-treatment difference in miR-126 of 65 at a two-sided 0.05 significance level. This is based our pilot data that demonstrated a standard deviation of the change in miR-126 pre- and post-treatment of 190. In our pilot data the mean change in miR-126 was 125 and a change of 65 was deemed an acceptable level of detection.
Rat model of nephrotoxic nephritis (NTN)

NTN was induced by raising a nephrotoxic serum (NTS) in rabbits to isolated sonicated rat glomeruli which was then injected into male Sprague-Dawley rats (1mL/200 g). A telescoped model of NTN was used where the rats are pre-immunised with 1 mg rabbit immunoglobulin before the injection of NTS (Holdsworth et al., 1981).
