HOW COLD DARK MATTER THEORY EXPLAINS MILGROM’S LAW

MANOJ KAPLINGHAT AND MICHAEL TURNER

Received 2001 August 8; accepted 2002 March 8; published 2002 March 19

ABSTRACT

Milgrom noticed the remarkable fact that the gravitational effect of dark matter in galaxies only becomes important where accelerations are less than about $10^{-8}$ cm s$^{-2}$ $\sim cH_0$ ("Milgrom’s law"). This forms the basis for modified Newtonian dynamics, an alternative to particle dark matter. However, any successful theory of galactic dynamics must account for Milgrom’s law. We show how Milgrom’s law comes about in the cold dark matter theory of structure formation.

Subject headings: dark matter — galaxies: fundamental parameters — galaxies: halos — galaxies: kinematics and dynamics — galaxies: spiral — gravitation

1. INTRODUCTION

The dark matter mystery has been with us since F. Zwicky noticed that the gravitational action of luminous matter is not sufficient to hold clusters together (Zwicky 1933; Smith 1936). V. Rubin and others brought the problem closer to home by showing that spiral galaxies like ours suffer the same problem (see, e.g., Kormendy & Knapp 1987). While the leading explanation for the dark matter problem today is slowly moving, weakly interacting “nonluminous” elementary particles remaining from the earliest moments—cold dark matter (CDM; see, e.g., Turner 2000)—there is still interest in the possibility that the explanation involves new gravitational physics (see, e.g., Sellwood & Kosowsky 2000).

Any gravitational explanation must deal with the fact that the shortfall of the Newtonian gravity of luminous matter occurs at widely different length scales—at distances much less than 1 kpc in dwarf spiral galaxies to distances greater than 100 kpc in clusters of galaxies. Merely strengthening gravity beyond a fixed distance cannot explain away the need for dark matter.

In 1983, Milgrom (1983a, 1983b) made a remarkable observation: the need for the gravitational effect of nonluminous (dark) matter in galaxies arises only when the Newtonian acceleration is less than about $a_0 = 2 \times 10^{-8}$ cm s$^{-2}$ $\sim 0.3H_0$. (Here $H_0 = 70 \pm 7$ km s$^{-1}$ Mpc$^{-1}$ is the present expansion rate of the universe.) This fact, which we will refer to as Milgrom’s law, is the foundation for his modified Newtonian dynamics (MOND) alternative to particle dark matter. It is not our claim that the analysis to follow rules out MOND.

The correctness or incorrectness of MOND aside, the empirical fact that the need for dark matter in galaxies always seems to occur at an acceleration of around $cH_0$ must be explained by a successful theory of structure formation. This Letter shows how Milgrom’s law arises in the CDM theory of structure formation.

2. HOW CDM PREDICTS MILGROM’S LAW

2.1. CDM Theory

The CDM theory of structure formation has two basic features: seed density inhomogeneity that arose from quantum fluctuations during inflation and dark matter existing in the form of slowly moving particles left over from the big bang. The two leading candidates for the CDM particle are the axion and the neutralino. Each is predicted by a compelling extension of the standard model of particle physics motivated by particle physics considerations (rather than cosmological) and has a predicted relic density comparable to that of the known matter density (see, e.g., Turner 2000).

A recent estimate of the matter density puts the total at $\Omega_m = 0.330 \pm 0.035$ and baryons at $\Omega_b = 0.040 \pm 0.008$ (Turner 2001). This means that CDM particles contribute $\Omega_{\text{CDM}} = 0.29 \pm 0.04$ (less the contribution of neutrinos). (Croft, Hu, & Davé 1999 argue, based on the formation of small-scale structure, that neutrinos can contribute no more than about 10% of the critical density.)

For our purposes here, a less essential feature of CDM is the fact that the bulk of the critical density exists in the form of a mysterious dark energy ($\Omega_x = 0.66 \pm 0.06$; see, e.g., Turner 2001). While the existence of dark energy affects the details of structure formation enough that observations can discriminate between a matter-dominated flat universe and one with dark energy, for the purposes of showing how CDM predicts Milgrom’s law, dark energy and its character are not critical. This is because most galaxies formed while the universe was still matter-dominated and well described by the Einstein–de Sitter model.

In the CDM scenario, structure forms from the bottom up, through hierarchical merging of small halos to form larger halos (see, e.g., Blumenthal et al. 1984). The bulk of galactic halos formed around redshifts of 1–5, with clusters forming at redshifts of 1 or less, and superclusters forming today. Within halos, baryons lose energy through electromagnetic interactions and sink to the center, supported by their angular momentum. Until baryonic dissipation occurs, baryons and CDM particles exist in a universal ratio of $\Omega_{\text{CDM}}/\Omega_b \approx 7$. Were it not for the concentration of baryons caused by dissipation, the gravity of dark matter would be dominant everywhere.

2.2. CDM and Milgrom’s Law

The CDM explanation for the gravitational effect of dark matter “kicking in” at a fixed acceleration approximately equal to $cH_0$ involves three ingredients: (1) the fact that the universe is reasonably well described by the Einstein–de Sitter model during the period when galaxies form, (2) the scale-free character of the seed density perturbations over the relevant scales, (3) baryonic dissipation, and (4) numerical coincidences.
The argument begins with facts 1 and 2, which lead to the CDM prediction of self-similar dark matter halos. Halos, regardless of their mass, can be described by the same mathematical form (Navarro, Frenk, & White 1997, hereafter NFW). The exact functional form is not essential (see below); for simplicity, we write the halo profile for an object that began from perturbations of comoving length scale $L$ as

$$
\rho_c(r) = \beta^3 \Omega_m \rho_{crit}(1 + z_c)^3/(rL)^2 = \beta \Omega_m \rho_{crit}(1 + z_c)/(rL)^2,
$$

where $\rho_{crit}$ is $3H_0^2/8\pi G$ is the critical density today, $z_c$ is the redshift of halo collapse, and $\beta$ is a numerical constant of $O(5)$. The physical size of the perturbation after collapse ($\equiv l$) is related to its comoving size, $l = L/\beta(1 + z_c)$; the factor of $1/(1 + z_c)$ is due to the expansion of the universe, and the factor of $1/\beta$ is due to collisionless collapse. Because $\Omega_m(1 + z_c)^3 \rho_{crit}$ is the mean matter density at the redshift of collapse, equation (1) says that the mean density of the collapsed structure interior to $r = l$ is about 100 times the ambient density when collapse occurred.

The redshift of collapse is determined by the spectrum of density perturbations: collapse on length scale $L$ occurs when the rms mass fluctuation on that scale ($\equiv \sigma_8$) is of order unity. Neglecting nonlinear effects, $\sigma_8$ at redshift $z$ is related to the matter power spectrum today ($\equiv \delta_0^2$):

$$
\sigma_8(z) = \left[ \int_0^\infty \frac{k^2 |\delta(k)|^2}{2\pi} |W_L(k)|^2 \, dk \right]^{1/2} \approx (e/10^{-5})(1 + z)^{-1}(L/L_0)^{(-1/2}\times n_{eff} + 3),
$$

where $k \sim L^{-1}$, $W_L(k)$ is the Fourier transform of the top-hat window function, and $n_{eff} \approx -2.2$ is the logarithmic slope of $L^2 \delta_0^2 \sim |\delta_0^2|$ (with respect to $k$) around galaxy scales. The quantity $\epsilon$ is the dimensionless amplitude of the primordial fluctuations in the gravitational potential, determined by COBE to be about $10^{-5}$, and $L_0 = 10 h^{-1}$ Mpc is the scale of nonlinearity today (for $\epsilon \sim 10^{-5}$). Substituting equation (2) into equation (1), it follows that

$$
\rho_c(r) = [(3\beta^3/8\pi)\Omega_m(e/10^{-5})] \times (H_0^2/2)(L/L_0)^{(-1/2}\times n_{eff} + 3) (rL)^{-2}.
$$

The third ingredient is baryonic dissipation; after halos form, their baryons dissipate energy and collapse in linear scale by a factor $\approx 10$ to form a disk supported by angular momentum (see, e.g., Dalcanton, Spergel, & Summers 1997). The degree of baryonic collapse is determined by the dimensionless spin parameter $\lambda$, which is the ratio of the angular velocity of the galaxy to the angular velocity that would be required to support the structure purely by rotation. The angular momentum of galaxies is thought to arise from tidal torquing (Peekies 1969 and references therein). Theory and simulations (Warren et al. 1992) seem to agree that $\lambda$ is independent of scale, with a median value of $\lambda \approx 0.05$. If one assumes that the angular momentum of the gas is conserved during disk formation, then (see Padmanabhan 1993) $\alpha \approx \Omega_m \lambda_0^2/\Omega_m \lambda_c^2$, which is about 12 because the disk spin parameter $\lambda_0 \approx 0.5$.

Because of the increased concentration of baryons interior to $r \sim l(\Omega_b/\Omega_{CDM})$, their gravity will dominate the dynamics in the inner regions. (This statement is true as long as $\alpha > \Omega_{CDM}/\Omega_c$.) Thus, the transition from dark matter-dominated gravity to luminous matter-dominated gravity should occur around $r_{DM} = L/\beta(1 + z_c)$. The acceleration at the point when dark matter gravity begins to dominate is

$$
a_{DM} = a(r_{DM}) = \frac{GM(r_{DM})}{r_{DM}^2} = [4\pi G/(l/7)]\rho_c(l/7).
$$

After some rewriting, Milgrom’s law emerges:

$$
a_{DM} = cH_0 \left[ \frac{10}{10^{-5}} \Omega_m \right] \left( \frac{c}{H_0} L_0 \right)^{2/3} (L/L_0)^{(-n_{eff} - 2)}.
$$

The final ingredient is the conspiracy of numerical factors to give a coefficient of unity and a very mild scale dependence (over 3 orders of magnitude in mass, $a_{DM}$ changes by only a factor of 1.6).

We have assumed in the above discussion that most of the baryons in the protogalaxy dissipate and form disks. How valid is this assumption? Clearly some of the baryons will be inhibited from collapsing by the UV radiation field or blown away into the intergalactic medium because of feedback from supernovae and possibly other phenomena related to star formation. It is sensible to assume that these effects are more pronounced for smaller mass galaxies. However, so long as the fraction of baryonic matter that collapses does not vary strongly with scale, our analysis goes through with only numerical factors changing. In fact, if the collapsed fraction in a 0.1 Mpc galaxy (L denotes the luminosity) is about half that of an L galaxy, this would give rise to a scale dependence in $a_{DM}$ about the same as, but opposing the change, in equation (4)—leaving $a_{DM}$ essentially scale-free. Of course, at the low-mass end of the galactic scale, one could have a much smaller collapsed fraction that could introduce scatter or deviation in the $a_{DM}$ versus luminosity relation (even after taking into account the fact that on those small scales $n_{eff}$ is smaller than $-2.2$). In this case, an accurate derivation of Milgrom’s law will require more sophisticated models incorporating gasdynamics of the baryons.

The mild scale dependence of the acceleration where dark matter dominates is due to the fact that $n_{eff} \approx -2$, around galactic scales. It arises from a combination of the primordial spectral index ($n = 1$) and the bending of the shape of the spectrum of perturbations caused by the fact that perturbations on small scales ($k \approx 0.1$ Mpc$^{-1}$) entered the horizon when the universe was radiation-dominated and those on large scales ($k \approx 0.1$ Mpc$^{-1}$) entered the horizon when the universe was matter-dominated. For $k \ll 0.1$ Mpc$^{-1}$, $n_{eff} \to 1$, and for $k \gg 0.1$ Mpc$^{-1}$, $n_{eff} \to -3$.

Returning to the numerical conspiracy that leads to $a_{DM} \approx cH_0$, for $n_{eff} = -2$, the factor $(e/10^{-5})L_0$ is just the scale of nonlinearity today, independent of the actual value of $\epsilon$. The numerical coincidence then is the fact that the scale of nonlinearity today is much less than the Hubble scale. Scott et al.
(2001) have tied this fact to the cooling scale of baryons, which can be related to fundamental constants and $\epsilon$. Equation (4) only holds around galaxy scales ($L \sim 1$ Mpc), where $n_{\text{eff}} \approx -2$ and $a \sim 10$. Clusters are dark matter-dominated almost everywhere because cluster baryons do not dissipate significantly. Milgrom’s law would, therefore, assert that the Newtonian acceleration in clusters should be less than $cH_0$ almost everywhere—in contradiction with observations. Said another way, CDM correctly predicts that Milgrom’s law should not apply to clusters.

The issue of the shape of the halo density profile is not central to our arguments. We have repeated our calculation for the NFW profile and find $a_{\text{DM}} \approx 10^{-3}(M_{200}/10^{12} M_\odot)^{0.1} \text{ cm s}^{-2}$, which is similar to the result obtained in equation (4) ($M_{200}$ is the mass interior to the point where the density is 200 times the critical density). MOND automatically predicts asymptotically flat rotation curves; in CDM the flatness of rotation curves has its origin in the fact that over a significant portion of the halo, $\rho_{\text{halo}} \propto r^{-3}$. The NFW halo profile asymptotes to $\rho_{\text{halo}} \propto r^{-3}$ so that CDM predicts $\nu_{\text{circular}} \sim [\ln (r/a)]^{1/2}$.

Another coincidence for CDM is known. The galaxy-galaxy correlation function is very well fitted by a power law, $\xi(r) = (\langle r \rangle)^{-1.8}$, where $\langle r \rangle = 5 h^{-1}$ Mpc (see, e.g., Groth & Peebles 1977; Baugh 1996). In CDM theory, the two-point correlation function of mass is not a good power law; however, when bias is taken into account (the nontrivial relation between mass and light), the galaxy-galaxy correlation function turns into a power law (see, e.g., Pearce et al. 1999), in good agreement with observations.

3. CONCLUDING REMARKS

The derivation of equation (4) is the key result of this Letter. It illustrates how Milgrom’s law—the need for dark matter in galaxies at accelerations less than about $cH_0$—arises in CDM theory. While scale-free density perturbations, an epoch where the universe is well described by the Einstein–de Sitter model, and baryonic dissipation are essential, the fact that $a_{\text{DM}}$ is nearly $cH_0$ appears to be a numerical coincidence. Furthermore, $a_{\text{DM}}$ is a fixed number since galaxies are bound and well relaxed today, while $cH_0$ decreases with time. Thus, the approximate equality of $a_{\text{DM}}$ with $cH_0$ only holds today.

The purpose of our Letter is to illustrate the basic physics that underlies the emergence of Milgrom’s law within CDM theory. It was not our intention to present a detailed analysis. To achieve our purpose we made some strong—but we believe reasonable—assumptions. The strongest of these assumptions is that all the baryonic matter associated with galaxies dissipates and collapses. This is probably not true, as significant amounts of baryonic material still exist in hot gas (Fukugita, Hogan, & Peebles 1998). However, so long as the fraction of baryonic matter that collapses does not vary much with scale (which we have quantified in § 2), our analysis goes through with only numerical factors changing. If the fraction of baryonic matter that collapses does vary dramatically with scale, one would expect deviant objects and scatter. We remind the reader that a detailed, semianalytic calculation of galactic rotation curves in CDM (van den Bosch & Dalcanton 2000) clearly shows the presence of a characteristic acceleration scale (of the order of $cH_0$), and they fit the data about as well as those derived from MOND. (We would argue that eq. [4] is the underlying explanation for the appearance of this acceleration scale.) Furthermore, a study of about 1000 spiral galaxies (Persic, Salucci, & Stel 1996), with luminosities from about 0.1$L_*$ to $L_*$, is in agreement with $r_{\text{DM}}/l$ being approximately constant.5 We have verified that for these galaxies the variation in $a_{\text{DM}}$ over the 1 order of magnitude range in luminosity is less than 20%. Both of these studies lend credence to our underlying assumptions.

Separating the important clues from the misleading coincidences is at the heart of scientific creativity. Hoyle’s observation that the energy released in burning 25% of the hydrogen to helium is approximately equal to that of the CMB suggested a non–big bang origin for the CMB (see, e.g., Burbidge & Hoyle 1998). In the end, it turned out to be a misleading coincidence. Within the big bang model, Hoyle’s coincidence is explained by the near equality of the dimensionless amplitude of density perturbations $\epsilon$ and the product of the efficiency of nuclear burning times $Q_\odot$ to make stars by the present epoch, $\Omega_\odot$, be $\sim \epsilon$, which coincidentally is equal to the energy that would be released in producing the observed helium abundance (M. J. Rees 2001, private communication).

CDM not only predicts Milgrom’s law (at least over an order of magnitude range in luminosity from 0.1$L_*$ to $L_*$) but also accounts for a wealth of other cosmological observations. This suggests to us that Milgrom’s law is a misleading coincidence rather than evidence for a modification of Newtonian dynamics.

This work was supported by the Department of Energy (at University of Chicago and Fermilab), NASA (grant NAG5-10842 at Fermilab), and the NSF (grant PHYS-0079251 at University of Chicago). We thank Martin Rees for stimulating conversations and Arthur Kosowski, Douglas Scott, and Frank van den Bosch for useful comments.
