(Dated: September 26, 2014)

Quasiparticle properties in the superconducting state are masked by the superfluid and are not directly accessible to infrared spectroscopy. We show how one can use a Kramers-Kronig transformation to separate the quasiparticle from superfluid response and extract intrinsic quasiparticle properties in the superconducting state. We also address the issue of a narrow quasiparticle peak observed in microwave measurements, and demonstrate how it can be combined with infrared measurements to obtain unified picture of electrodynamic properties of cuprate superconductors.

I. INTRODUCTION

Infrared spectroscopy has in the past several decades become one of the premier experimental tools in condensed matter physics.20 Thanks to its versatility, it has been successfully applied to essentially all types of condensed matter systems, such as superconductors, topological insulators, graphene, etc. In particular, in high-\(T_c\) cuprate superconductors, infrared based techniques have been extensively used to probe a variety of unusual and yet unresolved issues concerning their unconventional pairing state.21 In recent years a number of attempts has been made to elucidate the properties of quasiparticles and their relaxation in the cuprates.22 These attempts are based on the so-called extended-Drude model, which allows both the quasiparticle scattering rate and their effective mass to acquire frequency dependence. These two quantities can be straightforwardly obtained from the complex optical conductivity \(\tilde{\sigma}(\omega) = \sigma_1(\omega) + i\sigma_2(\omega)\) as:

\[
\frac{1}{\tau(\omega)} = \frac{\omega_p^2}{4\pi} \left[ \frac{1}{\tilde{\sigma}(\omega)} \right] = \frac{\omega_p^2}{4\pi} \frac{\sigma_1(\omega)}{-\sigma_1^2(\omega) + \sigma_2^2(\omega)} \tag{1}
\]

\[
\frac{m^*(\omega)}{m_b} = \frac{\omega_p^2}{4\pi} \left[ \frac{1}{\tilde{\sigma}(\omega)} \right] \frac{1}{\omega} = \frac{\omega_p^2}{4\pi} \frac{\sigma_2(\omega)}{-\sigma_1^2(\omega) + \sigma_2^2(\omega)} \tag{2}
\]

where the plasma frequency \(\omega_p^2 = 4\pi e^2 n/m_b\) is usually obtained from the integration of \(\sigma_1(\omega)\) up to the frequency of the onset of interband absorption:

\[
\omega_p^2 = 8 \int_0^{\omega_b} \sigma_1(\omega) d\omega \tag{3}
\]

Equations \(1\) and \(2\) are the basis of a so-called one-component approach for the interpretation of optical properties, which assumes the existence of a single type of charge carriers in the system. Closely related quantities are the optical self-energy \(\tilde{\Sigma}^{opt}(\omega)\) and memory function \(\tilde{M}(\omega)\) defined as:

\[
\tilde{M}(\omega) = 2\tilde{\Sigma}^{opt}(\omega) = \omega (\frac{m^*(\omega)}{m_b} - 1) + i \frac{1}{\tau(\omega)} \tag{4}
\]

As an example, in Fig. 1 we displays the real and imaginary parts of the memory function \(\tilde{M}(\omega)\), as well as the effective mass \(m^*(\omega)/m_b\) for optimally doped \(\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8+\delta\) (Bi2212) with \(T_c = 92\) K, both in the normal and superconducting state. Application of Eqs. \(1\) \(2\) and \(4\) to the data in the superconducting state is highly problematic, even though it has been routinely done. Namely, in the superconducting state normal fluid coexists with the superfluid, and the one-component assumption is clearly violated. As was most recently pointed out by Homes et al., this procedure cannot be used to make any reliable statements about quasiparticle properties in the superconducting state. In the superconducting state the response at microwave and far-infrared frequencies is dominated by the superfluid, causing \(\sigma_2(\omega) \gg \sigma_1(\omega)\) (Ref. [10]) and it follows from Eq. \(1\) that \(1/\tau(\omega) = M_2(\omega) \sim 1/\sigma_1^2(\omega)\) acquires small values (see Fig. 1). Similarly, indiscriminate application of Eq. \(2\) to the optical conductivity in the superconducting state will result in \(m^*(\omega)/m_b \sim 1/\sigma_2(\omega)\) which decreases when the superfluid forms, and \(\sigma_2(\omega)\) increases (see Fig. 1).

In this work we show how to circumvent this problem, and access intrinsic quasiparticle properties in the superconducting state. The procedure expands the range of applicability of one-component approach, and further extends the power of infrared spectroscopy. Our procedure is based on Kramers-Kronig transformation of the optical conductivity. In the next section (Sec. II) we first present the formalism in details. In Sec. III we apply it to model data, which serves to illustrate the main idea and demonstrate its usefulness. The procedure is then applied to existing infrared data on optimally doped high-\(T_c\) superconductor Bi2212 with \(T_c = 92\) K (Sec. IV). We present and discuss the quasiparticle properties obtained for the first time below \(T_c\). In this section we also address the issue of a narrow quasiparticle peak that has been observed in microwave spectroscopy, and show how it can be combined with infrared data to obtain a unified
\[ \sigma_2^{SC}(\omega) = \rho_s \frac{1}{\omega} + \sigma_2^{qp}(\omega) \]  

where \( \rho_s = \omega_s^2 = \omega(\sigma_2^{SC}(\omega) - \sigma_2^{qp}(\omega)) \).  

III. MODEL CALCULATIONS

To test the procedure and to demonstrate its usefulness in this section we perform the calculations on model data. We adopt a Drude model for the normal state, and a BCS model for an s-wave superconductor in the superconducting state. The model also includes a quasiparticle peak inside the superconducting gap. The critical temperature was set at \( T_c = 90 \text{ K} \), and the corresponding \( T = 0 \) energy gap is \( 2\Delta = 220 \text{ cm}^{-1} (27.3 \text{ meV}) \). Real and imaginary parts of \( \sigma(\omega) \) are shown with thick lines at several temperatures in Fig. 2(a) and (b) respectively. In the superconducting state a characteristic suppression of \( \sigma_1(\omega) \) is observed below the gap. The spectral weight removed from these frequencies is transferred to the delta function at zero frequency (Eq. 5). The values of plasma frequency are calculated from Eq. 3 and displayed in Fig. 2(c) with red circles. Note that in Eq. 3 the integral starts from 0+, which emphasizes the fact that in the superconducting state only the quasiparticle contribution should be counted towards \( \omega_p \). On the other hand, \( \sigma_2(\omega) \) is dominated by a characteristic \( 1/\omega \) response of the superfluid (Eq. 6). We also note that the absolute values of \( \sigma_2(\omega) \) are at least an order of magnitude larger than \( \sigma_1(\omega) \).
We now apply the procedure outlined in the previous section. In Fig. 2(b) with thin lines we display \( \sigma_2^{qp}(\omega) \) calculated from Eq. 4. We note that these Kramers-Kronig corrected curves are not dominated by \( 1/\omega \) superfluid response, but instead display a broad peak at finite frequencies, similar to the one seen at 90 K. The removal of superfluid response also reveals pronounced structure at the gap frequency, which is not observable in \( \sigma_2^{SC}(\omega) \) (before the correction).

In Fig. 2(c) we display with blue lines the results for the real (top panels) and imaginary (bottom panels) parts of the memory function \( M_i(\omega) \) from Eq. 4. In the normal state both parts display constant values, typical of the Drude model. On the other hand, in the superconducting state, \( M_1(\omega) \) is suppressed at higher frequencies, but does not show any characteristic features at the gap, because the response is dominated by the superfluid. The imaginary part \( M_2(\omega) \) displays characteristic suppression, especially below the gap. In the same figure we also plot with red lines the results for the memory function obtained with Kramers-Kronig-corrected \( \sigma_2^{qp}(\omega) \). Expectedly, in the normal state the memory function is the same as before. However, in the superconducting state, the removal of the superfluid contribution reveals a very pronounced structure at the gap frequency in \( M_1(\omega) \). The imaginary part \( M_2(\omega) \) also displays structure at the gap frequency, but more importantly the suppression below the gap is much smaller then before. Above the gap \( M_2(\omega) \) is enhanced compared to the normal state.

In Fig. 2(c) we display the temperature dependence of the plasma frequency \( \omega_p \) (red circles) obtained from Eq. 5 and the superfluid density (blue squares) obtained from Eq. 8. As discussed above, the spectral weight removed form finite frequencies is transferred to the delta function at zero energy, but the total spectral weight must be conserved. This is indeed confirmed by Fig. 2(c) where the total (i.e. combined) plasma frequency \( (\omega_p^2+\omega_s^2)^{1/2} \), is shown with green triangles and is constant within the error bars of numerical calculations. Note that the application of Eq. 8 to the normal state data results in a small, but finite value of superfluid in the normal state, above \( T_c \).

IV. BI2212

Before applying the procedure to Bi2212, we must address the issue of a very narrow quasiparticle peak that has been observed in microwave measurements\(^{12,13}\). Its width is typically a few meV, which is outside the...
frequency window of typical infrared measurements. The existence of this quasiparticle peak is usually ignored during analysis of infrared data, as it does not contain a lot of spectral weight and does not significantly affect the calculation of normal state plasma frequency (Eq. 3). However, this narrow peak can produce a significant 1/ω contribution to σ2(ω), which mimics the superfluid response. If we want to calculate the London penetration depth or the superfluid stiffness, it must be separated from the superconducting contribution. We show below that in the case of optimally doped Bi2212 this can lead to correction of superconducting plasma frequency ωp by as much as 40%.

In order to perform the integration in Eq. 7 optical conductivity data must be extended down to zero frequency. It was recently shown that because of the Kramers-Kronig relations between σ1(ω) and σ2(ω) one can calculate the spectral weight that is located below the lowest measured frequency \( \omega_{\text{min}} \). However, the optical functions themselves (σ1(ω) and σ2(ω)) cannot be retrieved without making some model assumptions about the optical spectrum. Here we will make the reasonable assumption that the quasiparticle contribution can be approximated with the Drude model, and we combine it with the microwave data on Bi2212. Fig. 4 displays σ1(ω) from infrared, as well as the microwave values at 34.7 GHz \( \simeq 1.15 \) cm\(^{-1}\) (the values at 14.4 and 24.6 GHz are similar\(^{12}\)).

We now fit the complex conductivity \( \sigma(\omega) \) simultaneously with microwave data, imposing the constraint that the total spectral weight in the superconducting state is conserved\(^{12}\). In Fig. 4 the infrared data is shown with thick lines, and model fits with dotted lines. The microwave values for the corresponding temperatures are shown with the circles of the same color.

With optical conductivity extended down to zero frequency we can now apply the procedure to Bi2212 and the results are shown in Fig. 4(b) with thin lines (only below \( T_c \)). We can see that instead of a characteristic 1/ω divergence, the spectra display a finite frequency peak, characteristic of quasiparticle response. The values of normal state plasma frequency \( \omega_p \) and superconducting plasma frequency \( \omega_s \) are shown in Fig. 4(c) with red circles and blue squares, respectively. The total plasma frequency \( (\omega_s^2 + \omega_p^2)^{1/2} \) (green triangles) is within 1.5% of the normal state value. Also shown with empty squares is the superconducting plasma frequency calculated using un-corrected \( \sigma_2(\omega) \), which can be as much as 40% higher than the corrected one.

Once the superfluid contribution is removed from \( \sigma(\omega) \), one can calculate intrinsic quasiparticle properties (Eqs. 1, 2 and 3). Fig. 5 displays M1(ω) (top panels), M2(ω)=1/τ(ω) (middle panels) and effective mass \( m^*(\omega)/m_0 \) (bottom panels), both before (blue lines) and after Kramers-Kronig corrections (red lines). Several selected temperatures are shown, both in the normal (100 K) and superconducting state (80, 50 and 10 K). Expectedly, optical functions in the normal state are the same before and after Kramers-Kronig correction. In the superconducting state, on the other hand, the corrections are significant and cannot be neglected. We note that even though the plasma frequency \( \omega_p \) decreases in the superconducting state (Fig. 5(c)), all optical functions are enhanced compared to their un-corrected values. In addition, the structure at around 700 cm\(^{-1}\) is much more pronounced in all corrected spectra. The reason is the removal of superconducting contribution from \( \sigma_2(\omega) \), which exposes the true quasiparticle properties.

In Fig. 6 we display the temperature dependence of quasiparticle scattering rate and effective mass, both before (blue circles) and after (red circles) Kramers-Kronig correction. The values of scattering rate were extracted...
as the average values at around 30 cm$^{-1}$. On the other hand the values of the mass were obtained from the linear fits of the low frequency $M_1(\omega)$ spectra (Eq. 4). This method has proven to be more reliable then a simple extrapolation, in particular in the normal state. The temperature dependence of scattering rate is similar before and after the correction, however the suppression of $1/\tau(\omega)$ below $T_c$ is much less pronounced after the correction. On the other hand, the effective mass reveals dramatically different behaviour. Before Kramers-Kronig correction the mass decreases in the superconducting, as anticipated above. However, once the superfluid and the true quasiparticle properties are exposed, we can see that the effective mass actually increases as temperature decreases below $T_c$. This indicates that the correlations are getting stronger in the superconducting state.

V. SUMMARY

We presented a way of calculating intrinsic quasiparticle properties, such as memory function and effective mass, in the superconducting state. The procedure allows access to the quasiparticle properties that were previously inaccessible to infrared spectroscopy. The method was first tested on model data, and then applied to infrared data on optimally doped Bi2212. The calculations have revealed that intrinsic quasiparticle scattering rate and effective mass are enhanced in the superconducting state. In particular, the effective mass increases below $T_c$ compared with the normal state values. This indicates that thermally excited quasiparticles in the superconducting state are more correlated than in the normal state.
In the cuprates, the superfluid density is not as high as in

irfrared measurements
This finding is in apparent contradiction with previous
the superconducting state diverges as doping is reduced.
Another important issue is the controversy regarding the
doping dependence of the quasiparticle effective mass.
Namely it was recently show using quantum oscillations
that the quasiparticle effective mass in YBa$_2$Cu$_3$O$_{6+x}$ in
the superconducting state diverges as doping is reduced.
This finding is in apparent contradiction with previous
infrared measurements. Using Hall data to discriminate
between carrier density $n$ and effective mass $m^*$
