Abstract

Background: Hypocalcemia is a frequent complication in patients undergoing thyroid surgery. It compromises the patient’s quality of life and increases hospitalization time, costs and mortality. The use of predictive factors to diagnose post-surgical hypocalcemia, allows early management, avoids complications and reduces treatment cost.

Methods: The MEDLINE/Pubmed and EMBASE databases were searched on May 2017. Meta-analysis, systematic reviews, observational studies and narrative reviews were included. The search was strengthened by reviewing the list of references of the selected publications and determining the relevant sources to be included manually in this publication.

Results: To assess patients for hypoparathyroidism, intact parathyroid hormone (iPTH), total serum calcium (TSC) and albumin levels, should be measured during the first 24 hours after the surgery. Patients can be classified into three groups: low-risk, medium/indeterminate risk, and high-risk.

Initiating prophylactic oral elemental calcium, the first day after surgery can reduce the incidence of postoperative hypocalcemia, the length of hospital stay and the need for parenteral calcium. The prescription of vitamin D (VD) is also recommended.

Conclusion: Hypocalcemia secondary to hypoparathyroidism, is a frequent complication after thyroidectomy. Early diagnosis by assessing predictive factors can prevent hypocalcemia and decrease mobility and mortality. Early evaluation of iPTH and corrected serum calcium (CSC) after neck surgery, are the most appropriate tests to diagnose transitory and permanent hypoparathyroidism.

Summary

Hypocalcemia is a frequent complication in patients undergoing thyroid surgery. It increases the hospitalized time and costs, decreasing the quality of life and the risk of death. Recommendations are given for the prevention, diagnosis and treatment of hypoparathyroidism in patients undergoing total thyroidectomy.

Introduction

Hypocalcemia is one of the major complications of surgical interventions in the central neck (level VI) due to the small size of the parathyroid glands (PGs), their proximity and firm adherence to the thyroid, and the risk of compromising their blood flow during surgery.

Despite the expertise of surgeons, postsurgical hypocalcemia remains a prevalent complication in patients undergoing total thyroidectomy and / or central lymph node dissection, causing high postoperative morbidity and compromising the quality of life and increasing costs to the health system [1].

Some efforts have been made to find, intra and postoperative hypocalcemia predictors in an attempt to prevent and manage it early. Nevertheless, lack algorithms for its prevention, diagnosis and treatment. These algorithms could reduce the number of post-operative admissions to the emergency room, and improve morbidity.

We present a review of the literature on the prevention and early detection of post-surgical hypocalcemia; and also give some recommendations for the acute management of the patients undergoing thyroidectomy.

Anatomy and Physiology of the parathyroid glands: The PGs are small glands, brown colored, derived from the pharyngeal pouches and usually located on the dorsal side of the upper and lower poles of the thyroid gland. Given its embryonic origin, they may be located anywhere along the migration route of the pharyngeal pouches (carotid sheath, thymus or anywhere in the anterior mediastinum). They are usually (80% population) four in number although between 1-7% of people have 3 and between 3-6% have more than 4 PGs [2].

Irrigation to the superior upper PGs often depends on the superior thyroid artery (STA), and in some cases from a branch of
Clinical presentation

Signs and symptoms of hypocalcemia depend on the severity and the acuity of the onset. In acute hypocalcemia the first symptoms described are neurological; with paresthesias in the perioral region, hands and feet and if untreated progressing to cramps, hyperreflexia and muscle spasms. Irritability, depression and psychotic symptoms may be associated findings. In severe cases, angina pectoris, congestive heart failure or syncope, due to changes in contractility or cardiac electrical conduction may occur. Laryngospasm, bronchospasm or epileptic crises can also occur all of which compromising the patient’s life [36,37].

In the neurological examination it is important to remember the classical signs of latent tetany with positive Chvostek’s (present in 1-25% healthy subjects and in 94% of patients with true hypocalcemia, although it may be absent in chronic hypocalcaemia) and Trousseau’s signs (absent in a third of patients with hypocalcemia) [22,36,38].

Chvostek’s sign consists on the momentarily contraction of the ipsilateral side of the face (nose or lips) when the facial nerve is tapped at the angle of the jaw (the masseter muscle). Trousseau’s sign is considered more sensitive than Chvostek’s sign. It consists on the spasm of the hand and forearm due to the occlusion of the brachial artery when a blood pressure cuff is placed on the arm and inflated to 10 mm Hg above the systolic pressure during at least 2 minutes.

The most frequent electrocardiographic findings are QTc and ST segments prolongation, T wave inversion and in severe cases, AV block or ventricular fibrillation [22,38].

In chronic hypocalcemia symptoms such as dry skin, rough hair or fragile nails are often more subtle. In spite of that, severe complications may appear in chronic cases such as papilledema, parkinsonism, subcapsular cataracts, calcification of the basal ganglia and intracerebral hemorrhages [22,38].

Workup: The diagnosis of post-surgical hypoparathyroidism is made with CSC and iPTH levels. The determination of iPTH in blood sample during the first 24 hours after surgery allow a confident diagnosis of a temporary parathyroid dysfunction [39]; the measurement serum calcium alone cannot predict hypoparathyroidism, because > 50% of patients with iPTH levels of < 10 pg/mL had a CSC of > 8 mg/dL (2 mmol/L) on the first postoperative morning [40].

Other lab tests are important in the evaluation of the patient suspected with this condition: [9,10,22,33,38]

- Serum phosphorus levels: May be increased in hypoparathyroidism, but low in hungry bone syndrome.
- Vitamin 25 hydroxy-D3: Levels in the insufficiency of deficiency ranges contribute to hypocalcaemia.
- Serum magnesium: Levels compromise management of hypocalcaemia, normal levels are required for proper PTH secretion.

In some cases, with unexpected clinical complications is important to assess acid-base status as the presence of alkalosis increases the binding sites of the albumin to calcium, thus reducing the proportion of free calcium and causing symptoms of hypocalcaemia; in these cases, measurement of CSC is not useful, and determination of ionized calcium is highly recommended.

The main risk factors for postsurgical hypoparathyroidism are:

- Large size and weight of the thyroid gland [17,21]
- Reto-ster nal extension of the thyroid [32]
- Dissection of the central neck nodal compartment [15,25,31]
- Re-interventions [17]
- Deficit or insufficiency of VD [33]
- Graves-Basedow disease [26,31]
- Extent of surgery [15,34]
- Female sex [15,31]
- Presurgical use of β Blockers [31]
- Less than 2 PGs identified [15]
- Parathyroid tissue on the final pathology report [35]
Predictive factors of postsurgical hypoparathyroidism:

a) Serum levels of iPTH

Serum iPTH levels take before, during and after thyroidectomy have been evaluated in different studies as a predictive factor for mild to severe post-surgical hypocalcemia and post-surgical hypoparathyroidism.

In a prospective multicentric study, it was found that preoperative iPTH levels equal to or higher than 47.9 pg/mL (5 pmol/L) were a predicting factor for recovery of parathyroid function [11], however, in a meta-analysis including 115 observational studies, the iPTH taken before surgery had no predictive value by itself in the multivariate analysis [31].

The decrease of the postoperative iPTH value compared with the preoperative, has been proven as a predicting factor of transient and permanent hypocalcemia [11,20,31]. Different values of iPTH defined as threshold taken at different latency times which can be as early as 5 minutes after thyroidectomy (intraoperative iPTH), in the first post-surgical hour (peri-operative iPTH) or at 24 hours post-surgical (post-operative iPTH), have been reported. Regarding levels of intraoperative iPTH, values < 9.5 pg/mL [41], < 10 pg/mL [42-45], < 11.3 pg/mL [46], < 12 pg/mL [47], < 18 pg/mL [48] have predicted hypocalcaemia postoperatively; but the most accepted threshold is < 10 pg/mL.

A decrease with respect to the preoperative baseline value of iPTH > 62.5% [48] measured at 10 minutes (intraoperative), or > 88% in the first hour (perioperative) [11,31], or 41.9% at 24 hours (postoperatively), accurately predicted postoperative hypocalcemia and may predict persistent hypoparathyroidism after 6 months of follow-up in the majority of patients. The possibility that these patients recover their parathyroid function completely is only 10% [11].

Decreased absolute values of iPTH within the first day postoperatively at 4 hours < 10 pg/mL [49,50] or at 24 hours < 5.8 pg/mL, are correlated with postoperative hypocalcemia [12,24]. Accordingly, levels > 7 pg/mL [20], > 9.8 pg/mL [12], > 15 pg/mL [24,28,47], could exclude the development of persistent hypoparathyroidism. However the majority of authors agree with the cutoff < 15 pg/mL (24,28,47).

In accordance with the majority of reports we conclude that postoperative iPTH levels < 10 pg/mL are predictors of hypocalcemia with a sensitivity of 72%-97.5%, specificity of 80%-99%, positive predictive value (PPV) of 53%-90% and a negative predictive value (NPV) of 80%-99% [11,16,45,51,52].

b) Serum calcium values: A statistically significant correlation between normal preoperative calcium levels and the presence of post-surgical hypocalcemia has not been found [31]. However, the progressive increase in serum calcium values between 6 and 24 hours after surgery, and the finding of normal post-surgical calcium levels, have a high NPV (80%-100%) ruling out the possibility of permanent hypocalcemia and hypoparathyroidism [13,19,31,45,51].

c) 25-Hydroxy-vitamin \(D_2\) levels: Low levels of \(VD\) increase the probability of hypocalcemia in the postsurgical period [30,33].

Prevention of postsurgical hypoparathyroidism: As previously described, the insufficiency or deficiency of \(VD\) is an independent preoperative predictor (Figure 1), contributing to postsurgical hypocalcemia. Its measurement is suggested routinely as a first step in preventing postoperative hypocalcemia [30,31]. The high cost is decreasing progressively, and its benefit supports its routine use.
calcium 3 gr/day (1gr tid) + calcitriol 1 µg/day (0.5 µg bid) starting in the first postoperative night and extended for two weeks is routine. Once normalized, weekly monitoring of CSC for albumin and phosphorus and titrating doses according to the reports is the generalized use [14,18,57].

Detection, diagnosis and management of hypoparathyroidism:
To assess the presence of hypoparathyroidism, the levels of iPTH, serum total calcium and albumin should be measured during the first 24 hours after surgery and the patients should be classified into 3 groups:

Low risk patients: Should iPTH levels be within normal limits (15 – 65 pg/mL) and CSC between 8-8.5 mg/dL, the patient may be discharged with an outpatient dose of 600 mg elemental calcium per day orally, and weekly clinical and lab tests surveillance.

Medium/indeterminate risk: For patients with CSC > 8 >8 mg/dL and iPTH between 5–15 pg/mL, they could receive elemental calcium 1200 mg/day and calcitriol 0.5 µg/day in divided doses for discharge. If the patient shows a CSC between 7.5-8 mg/dL and iPTH between 5-15 pg/mL we recommend elemental calcium of 2400 mg/day and calcitriol 1 µg/day in divided doses. CSC and phosphorus levels should be monitored and discharged when the calcium reaches levels above 8 mg/dL.

High risk patient: If the values of CSC are below 7.5 mg/dL, iPTH < 5 pg/mL it is advisable to start elemental calcium 3000-6000 mg/day and calcitriol 1.5-2 µg/day. If CSC levels is persistently below 7.5 mg/dL despite oral treatment or if patient is severely symptomatic, administer intravenous calcium gluconate in continuous intravenous infusion at an initial dose of 1 mg/kg/hour until achieving values > 7.5 mg/dL, and only then it would be possible to switch to oral therapy [16,30,31,60,61] Calcium gluconate (C₆H₁₂O₇) is available in 10 cc ampules (10%) containing 0.232 mmol/L of calcium ion (0.465 mEq/mL). EKG monitoring must be done during calcium infusion. (Figure 2).

It is also recommended to give VD additional to calcium when the patient does not take VD (cholecalciferol) supplements.

Outpatient management of hypoparathyroidism: Patients who fail to show normal levels of CSC and symptoms of hypocalcemia persist, can be used diuretic type thiazides if blood pressure is normal or elevated. Thiazide diuretics lower urine calcium excretion because they enhance renal calcium reabsorption, at the distal tubule [62]. They bind to the chloride site of the sodium/chloride cotransporter at the convoluted distal tubule. This inhibits NaCl resorption, promoting its excretion and decreasing the effective volume. This triggers proximal and sodium reabsorption, promotes the passive absorption of calcium and enhances the activity of the Na/Ca and increases calcium reabsorption through an active mechanism [63].

Figure 2. Approach to the acute patient with hypocalcemia after thyroid surgery. It is recommended to follow up and educational interventions to promote a healthy lifestyle with appropriate diet; improve adherence, and the proper use of drug therapy. PTH: Intact Parathyroid Hormone measured 6 to 24h postoperatively. TCa: Total calcium albumin-corrected value and expressed in mg/dL.

J Transl Sci, 2018 doi: 10.15761/JTS.1000212 Volume 4(2): 4-7
The hypocalciuric effect of thiazides is not just secondary to the effective volume depletion but depends upon the levels of PTH (near normal circulating hormone) and producing hypercalcemia due to the calcium release from the bone and probably increasing PTH action in the bone and kidney [64,65]. Follow up with serum levels of calcium, phosphorus and creatinine should be done weekly or monthly during initial dose adjustments. Once the levels are stable, follow up can be done twice a year. A 24-hour urine calcium should be done at least once a year after stable doses of supplements are established, and should be less than 4 mg/kg/24 hours.

New therapy options

Treatment with calcium andVD may be challenging and lead to complications such as calcification in soft tissues, hypercalcemia and hypercalciuria. In response to PTH deficit in these patients, it has been considered since 1929 (with the demonstration of doctor Albright), the utility of bovine PTH in the management of symptomatic hypocalcemia [66]. Many studies have been conducted with 2 molecules of recombinant human PTH, the amino terminal extreme, PTHR (1-34) (Teriparatide) [67] and the complete molecule PTHR (1-84) [68], both proving beneficial in maintaining serum calcium levels and bone mineral density in patients with postsurgical hypoparathyroidism refractory to calcium and VD treatment [69].

Treatment with PTHR (1-84) evidenced an increase in serum calcium levels (variable during the day) with a peak at 6-8 hours post injection, and increased activation of VD, 10 hours post administration [68]. Available PTHR (1-34) with a shorter half life, requires administration every 12 hours, or subcutaneous infusion per pump [70-72], while the molecule (1-84) can be administered every 24 hours [73,74].

In January 2015, the treatment of postsurgical hypoparathyroidism with recombinant PTH (1-84) was approved by the FDA with the brand name Natpara®. Its use as an adjunctive to treatment with VD and calcium in patients with postsurgical hypoparathyroidism was indicated only in patients which cannot be controlled with calcium plus VD or the active molecule of VD (Calcitriol or alfalcitriol), with the specification to individualize the treatment for each patient, given the evidence of increased risk of osteosarcoma in rats. Its prescription can only be made by qualified and trained personnel in NPS Advantage; with an initial dose of 50 µg/day.

Conclusion

Hypocalcemia secondary to hypoparathyroidism after thyroidectomy is a frequent complication morbidity and mortality. The use of predictive factors allows timely identification of patients at risk and the prevention of complications. Early monitoring of iPTH and corrected or ionized serum calcium levels after neck surgery, are the most appropriate tests used to diagnose transitory and permanent hypoparathyroidism. We present an algorithm for appropriate management of hypocalcemia prevention and treatment.
