ABSTRACT

Lymphoma is the third most common cancer diagnosed in children and T cell lymphoma has the worst prognosis by clinical observation. So far, a lymphoma model with uniform penetrance has not been available. In this paper, we generated a p53 deficient mouse model by targeting embryo stem cells derived from the C57BL/6 mouse strain. Homozygous p53 deficient mice exhibited more accelerated rate of spontaneous tumorigenesis with a high spontaneous occurrence rate (93.3%) of malignant lymphoma. Because tumour models with a high phenotypic consistency are currently needed, we further generated the lymphoma model by single intraperitoneal injection of 37.5 or 75 mg/kg N-methyl-N-nitrosourea (MNU) to p53 deficient mice. Lymphoma and retinal degeneration occurred in 100% of p53 +/- mice administrated higher concentration of MNU, which was much higher than previously reported models. The main anatomic sites of lymphoma were thymus, spleen, bone marrow, and lymph nodes. Both induced and spontaneous lymphomas in the thymus and spleen were stained positive for CD3 antigen. Furthermore, positive CD4 and/or positive CD8 cells were detected by flow cytometry, indicating a T-cell lineage of the lymphomas. The onset time of this uniform lymphoma model was from 13 to 17 weeks after the administration of MNU accompanied by the second time of weight loss. Based on our observations and previous data, we hypothesised that mice with the B6 background are prone to lymphomagenesis. This model could be used to study the mechanisms of lymphomagenesis, to select new drugs, and to improve the reproducibility of experimental results.

INTRODUCTION

Hodgkin lymphoma and non-Hodgkin lymphoma are the third most common cancer diagnosed in children worldwide [1]. Although the prognosis of patients has been significantly improved because of the progress of the study of the pathogenesis and new therapies, the overall outcomes of treatment remain poor. An appropriate animal model mimicking human disease conditions is crucial for facilitating our understanding of the basic mechanism of lymphoma pathogenesis as well as developing effective new anti-tumour drugs and treatment options. Various
lymphoma animal models have been reported, among which mouse models are the most popular. In the early 1970s [2], a transplantable tumour was injected into CBA mice to model Gardner lymphosarcoma. The generation of adult T-cell leukaemia/lymphoma [3] and human acute B-lymphoblastic leukaemia [4] by xenotransplantation of primary peripheral blood mononuclear cells into combined immunodeficient mice were reported recently. In addition to the use of immunodeficient mice, irradiation or thymectomy have also been used to optimize models [5]. Genetically modified mice have also been studied intensively as potential lymphoma models [6–10].

*p53* is a well-known tumour suppressor gene, *p53* knocked out mice appear spontaneous carcinogenesis [11]. A variety of tumours have been reported in *p53* mutant mice of different genetic backgrounds. Lymphoma was observed in 47% and 53% of homogenous *p53* deficient mice of the 129/Sv and BALB/c backgrounds, respectively [6, 7]. *p53* deficient mice of mixed C57BL/6 and 129/Sv backgrounds (75% C57BL/6 and 25% 129/Sv) exhibited 65%–75% incidence of lymphoma [6, 12]. Because a high percentage of tumours from *p53* mutant mice are lymphomas, *p53* mutant mice are regarded as a potential model for lymphoma pathogenesis study. However, its low penetrance ratio has hampered further mechanistic studies. Carcinogen-induced models have also been investigated to improve the incidence of lymphoma. When B6.129-Trp53 N5 heterozygous mice were subjected to N-methyl-N-nitrosourea (MNU) induction, 85% of mice developed lymphoma within six months [8].

In the present study, a uniform lymphoma model was established by deletion of the *p53* gene of the C57BL/6 background mice. Homozygous *p53* mutant mice were viable and 93.3% developed spontaneous lymphomas from 12 to 37 weeks. Furthermore, 100% heterozygous mice induced with 75 mg/kg of MNU developed lymphomas, and induced tumour incidence showed a dose-effect relationship with MNU. Lymphoblasts in thymic lymphomas stained positive for mouse CD3 antigen, and represented CD4 positive and/or, CD8 positive detected by flow cytometry, indicating a T-cell lineage.

**RESULTS**

**Generation of C57BL/6 mouse ES cells**

Although most ES targeting has been performed using ES cells on the 129/Sv background, an ES cell line isolated from the C57BL/6 inbred strain has the advantage of a much cleaner background and no need for reciprocal backcrossing. In this study, we used an ES cell line (Figure 1A) established from C57BL/6 mice to generate knockout mice. We examined the karyotype of ES cells and confirmed that they were male (XY) and the chromosome number was normal (Figure 1B). This ES cell line was reported to have high germline transmission efficiency. By using this highly efficient and hereditary stable C57BL/6 ES cell line, we generated *p53* gene knockout mice by ES targeting.

**Generation of p53Δ2-5/* mice**

A targeting vector containing a phosphoglycerate kinase (PGK) promoter driving a Neo cassette was generated. The Neo cassette replaced exon 2 to exon 5 of the *p53* gene, which accounted for approximately 40% of the coding region (Figure 1C). The *p53* targeting vector was electroporated into the established C57BL/6 ES cell line and ES cells were screened by G418. G418 resistant colonies were further confirmed by Southern blotting. The 5′probe hybridized to an EcoRI fragment of approximately 17 kb from the wild-type *p53* allele, whereas induction of the PGK-Neo cassette in a mutant allele contained another EcoRI site that yielded a 7-kb fragment (Figure 1D). Four heterozygous ES cell clones were subjected to blastocyst injection. A total of 151 wild-type BALB/c blastocysts were injected and 24 chimera mice were produced. The male chimera mice were crossed with C57BL/6 female mice and 37 F1 mice with black fur and 48 mice with white fur were obtained (Table 1). Some F1 male and female heterozygous mice were further intercrossed to generate homozygous *p53* gene knockout mice (Figure 1E).

The deletion of exon 2 to exon 5 theoretically abolished *p53* transcription. To prove that the *p53*Δ2-5/* allele was a null allele, the expression of *p53* gene was checked. We analysed total RNA derived from liver, spleen, lung, brain, and thymus. Heterozygous mice approximately exhibited half of the normal *p53* gene expression level observed in wild-type mice, whereas homozygous mice did not express *p53* mRNA at all. These results were confirmed by two independent pairs of primer, one pair primer located in exon 4 and 5, and the other located in exon 9 and 10 (Figure 1F). This model is named as B6-Trp53Δ2-5/*NIFDC, and is referred to as *p53*Δ/* in this study.

**High frequency of spontaneous lymphoma in p53Δ/* mice**

According to Knudson’s two-hit hypothesis [13], *p53*Δ/* mice of various genetic backgrounds develop spontaneous tumours much earlier than *p53*Δ/* mice [6, 7, 12, 14]. As shown in Figure 2A, *p53*Δ/* mice did exhibit more accelerated rate of tumorigenesis than that of heterozygous or wild-type mice. About 50% of *p53*Δ/* mice were moribund and euthanized for anatomic study before 26 weeks, and all died before 32 weeks. However, all the wild-type and 90% of *p53*Δ/* mice survived until the end of the study.

Necropsy showed obvious thymus enlargement in 23 of 30 mice. Microscopic observation found out...
that the most frequently observed tumour of the \( p53^{+/-} \) homozygotes was malignant lymphoma, affecting 28 of 30 tumour-bearing mice. Of the remaining 2 mice, one had rhabdosarcoma and the other had adenocarcinoma (Table 2). The tumour frequencies of malignant lymphoma, rhabdosarcoma, leiomyosarcoma, and adenocarcinoma were 93.3%, 13.3%, 10% and 3.3%, respectively (Figure 2B). These data implied that this model was susceptible to tumour development.

22 of 30 mice (73.3%) only developed lymphoma, 3 mice had both lymphoma and rhabdosarcoma, and 3 animals had both lymphoma and leiomyosarcoma. The relative frequency of lymphoma occurrence was 92.5%; the second most common tumour was rhabdosarcoma, accounting for 3.7% of all tumours (Figure 2C). The tumour spectrum was quite different from that observed for \( p53 \) gene knockout mice of different genetic backgrounds. Donehower reported that 10 kinds of tumours were observed [6, 11], while only four types of tumours were found in this homozygote of the B6 background, indicating \( p53^{+/-} \) mice on a C57BL/6 background predominantly developed lymphoma.

The anatomic sites of tumours included the spleen, thymus, liver, kidney, heart, lung, and stomach. As expected, malignant lymphoma occurred mainly in the spleen and thymus, with a rate of 70%, indicating the spleen and thymus were the primary organs of lymphoma in this model. Moreover, lymphoma was also observed

| 30   | ♂   | 24          | Malignant lymphoma | Spleen, liver, kidney, inguinal lymph node; |
frequently in the bone marrow, lymph nodes, liver, kidney, and heart, etc. (Figure 2D). Rhabdosarcoma was observed in muscle, adenocarcinoma was found in the jejunum, and two mice had leiomyosarcoma in the stomach.

Generation of a lymphoma model by MNU induction in \( p53^{-/-} \) mice

Since this \( p53^{+/+} \) mice with C57BL/6 background had higher occurrence of lymphoma (93.3%) than that of other strains [6, 12], we want to generate a lymphoma model with higher consistency and earlier occurrence. Genotoxic carcinogens are generally referred to as initiating agents of tumorigenesis because they damage DNA and induce mutations in key target genes, which is thought to be the initial event leading to cancer development [15]. MNU is a widely used positive genotoxic carcinogen for \( p53 \) deficient mice and other transgenic mice in carcinogenicity studies [8, 16]. Therefore, we used MNU to shorten the lymphoma occurrence time and to establish an efficient tumour model.

Wild-type, \( p53^{+/+} \), and \( p53^{-/-} \) mice were administered 37.5 mg/kg of MNU dissolved in citrate buffered saline adjusted to pH 4.5 by single intraperitoneal injection. All the \( p53^{-/-} \) mice died within one week post administration, while \( p53^{+/+} \) and wild-type mice survived until the end of the experiments (Figure 3A). Since tumors usually do not develop within a week, only wild-type and \( p53^{+/+} \) mice were further observed. The frequency of lymphoma occurrence was 65% in \( p53^{-/-} \) mice and 10% in wild-type mice (Figure 3B, \( P < 0.05 \)). Except for malignant lymphoma, no other types of tumours were observed (Figure 3C). The lymphoma frequency in different organs was shown in Figure 3D, and higher incidences of tumour were observed in the thymus and spleen.

To further test tumour incidence and uniformity of the model, a group of \( p53^{+-} \) mice were administered 75 mg/kg MNU by single intraperitoneal injection. The onset of tumorigenesis of \( p53^{+-} \) mice administrated 75 mg/kg MNU group was much earlier than that of \( p53^{-/-} \) mice administrated 37.5 mg/kg MNU. Because most animals died between 13 and 17 weeks, other survived animals were sacrificed by 23 weeks (Figure 4A). This result indicated that the increased MNU concentration could accelerate the development of tumour.

Microscopic findings showed that malignant lymphoma was the most predominant tumour, occurring in 100% of mice at the end of experiment. The second most common tumour was adenoma, with a rate of 43% (Figure 4B). Unlike other spontaneous tumour models, rhabdosarcoma and leiomyosarcoma were not observed. Figure 4C shows the tumour distribution in this animal group; as expected, the most common tumour was lymphoma (87%), and the proportion of adenoma was 13%.

We further investigated the incidence of lymphoma in different organs. Tumours were mainly present in the lymphoid organs, including the thymus (100%), spleen (100%), bone marrow (93%), mesenteric lymph nodes (57%), inguinal lymph nodes (57%), and mandibular lymph nodes (29%). Lymphoma was also found in some non-lymphoid organs, such as the kidney, lung, and liver (Figure 4D). In contrast to the 37.5 mg/kg MNU group (Figure 3D), the lymphatic system showed a high number of lesions, and the tumour incidence increased from 65% to 100%. With the advantage of easy sampling and high rate of lymphomagenesis, the thymus and spleen can be used as the most appropriate target organs for the study of mechanisms of lymphomagenesis.

Organ enlargement was observed frequently by gross pathological examination (Table 3), and the occurrence rate of thymus mass and enlarged spleen was higher than that of other organs. To investigate organ enlargement further, the weight of the heart, spleen, lung, kidney, brain, thymus, salivary gland, adrenal gland, ovaries, and uterus were measured. Figure 5 shows that the absolute weight and relative organ weight of the spleen and thymus were heavier in the 75 mg/kg MNU group than that of the control group (\( P < 0.05 \)).

T-cell lineage of the malignant lymphomas of thymus and spleen

To determine the cell origin of the malignant lymphoma, we performed immunohistochemistry staining of sections from 5 male and 5 female MNU-treated \( p53^{-/-} \) mice. (Figure 6A–6G) and 4 \( p53^{+-} \) mice diagnosed with spontaneous thymus and spleen malignant lymphoma using antibodies directed against CD3 (T lymphocyte marker), CD20 (B lymphocyte marker), and CD68 (macrophage marker). All neoplastic cells in thymus and spleen malignant lymphoma sections from animals with induced or spontaneous malignant lymphoma were positive for CD3 (Figure 6H, 6K) and negative for CD20 (Figure 6I, 6L) and CD68 (Figure 6J, 6M), indicating that the malignant lymphomas were of T-cell lineage, consistent with previous reports [8, 14]. To further confirm the cell origin, the whole thymic and splenic cells were isolated for flow cytometry assay. The lymphoma cells were TCR\( \beta^{+} \), TCR\( \gamma^{+} \), and NKP46- cells (data not shown). Further analysis indicated that CD4+ and CD8+ cells were observed in thymus and spleen from animals with lymphomas or wild type mice, but CD4 and CD8 double positive cells mainly found in thymus (Supplementary Figure 1A, 1B), only differentiated CD4+ or CD8+ population were found in spleen (Supplementary Figure 1C and 1D). The ratio of CD4+, CD8+, double positive, and double negative cell populations were different in \( p53^{-/-} \) mice with thymic lymphoma, to represent 29.2%, 15%, 31%, and 24% of total lymphocyte as compared with 12.3%, 6%, 74% and 5.3% in wild type mice, respectively (Supplementary Figure 1E), indicating lymphomagenesis might occur after the formation of CD4 and CD8 double
positive T lymphocyte [17]. The present observation was different to that of Donehower et al. [6], that is, both B and T lymphomas were found. The reason might be due to the different backgrounds of mice used in the studies.

Body weight, and haematological and biochemistry analyses

To examine the characteristics of the lymphoma model, we monitored the clinical features and body weight change from the time of MNU administration to death or sacrifice. We also measured haematological and blood biochemical parameters at the end of six months. Clinical symptoms, such as decreased activity, hunched back, listlessness, thinness, and rapid breathing patterns were observed at about 12–13 weeks after the administration of MNU. All animals administered citrate buffer (controls) did not show any clinical signs and survived until sacrifice. Mice administered 75 mg/kg MNU exhibited significantly decreased body weights compared with those administered citrate buffer at 2–3 weeks after dosing. This body weight loss may be caused by the acute toxicity of this chemical [5]. Although the body weight of mice administered MNU gradually recovered, it remained lower than that of citrate buffer control animals at most time points. A second body weight decrease occurred at 12–13 weeks post dosing (Figure 7), probably due to the progression of malignant lymphoma, which is in accord with the time of moribund/death of many animals (Figure 4A) and the appearance of clinical symptoms.

In the haematological analysis, we counted the total number of white blood cell, neutrophilic granulocyte, lymphocyte, monocyte, eosinophil, basophil and red blood cell, and calculated their relative percentages. We found the cell number of neutrophilic granulocyte were higher in the p53+/− MNU group than in the citrate buffer controls (P < 0.05), while the lymphocyte number and its relative percentage did not increase significantly (P > 0.05). The neutrophilic granulocyte increase might have resulted from systemic inflammatory responses occurring at the end stage of the tumour, because cellular infiltration was observed in various organs by histopathology. The red blood cell number, haemoglobin, and total protein was decreased significantly (P < 0.05) in the p53+/− MNU group. Four biochemistry parameters, triglyceride, urea, total cholesterol, and calcium, were increased and serum albumin and creatinine were decreased in the MNU group, compared with the citrate buffer group at the end of the experiment (Supplementary Figure 2).

Non-neoplastic microscopic findings in the p53+/− mouse lymphoma model

Non-neoplastic microscopic findings included adenomatous hyperplasia of the duodenum and jejunum, glandular hyperplasia of the duodenum, and retinal degeneration of eyes (Supplementary Figure 3). The characteristics of adenomatous hyperplasia and glandular hyperplasia included an increase of crypt length and the number of cells per crypt, lengthened villi, and increased diameter of crypts but without formation of the circumscribed area of the epithelium. Notably, 100% of mice administered MNU had retinal degeneration, indicating this animal model had high homogeneity.
DISCUSSION

Small, economical animal models have been widely used for the study of oncology mechanisms and the screening of therapeutic regimens [18]. An animal model with high phenotypic consistency may improve the reproducibility of experiments, reduce the number of animals required, and facilitate research on tumour pathogenesis. Here, we present a new lymphoma mouse model established by $p53$ gene deletion in mice of the C57BL/6 background followed by MNU administration. We found out that 100% $p53^{+/+}$ knockout mice administrated high dose of MNU developed lymphomas. Animal death was observed mainly from 13 to 17 weeks post MNU administration (Figure 4), indicating this lymphoma model has the feature of uniform tumorigenesis, predictable early onset time, and high reproducibility.

P53$^{-/-}$ spontaneous tumour

![Graph showing survival rates and tumour profiles]

**Figure 2:** Spontaneous lymphoma occurrence in $p53$ homozygous mice. (A) Survival curve of wild-type, $p53^{-/-}$ and $p53^{+/+}$ mice. All homozygous mice died before 32 weeks, while heterozygote and wild-type mice survived until 32 weeks. (B) Spontaneous tumour profile and frequency of $p53^{-/-}$. Malignant lymphoma was the most prominent type with an occurrence rate of 93.3%. (C) Relative frequency of malignant lymphoma, adenoma, rhabdosarcoma, and leiomyosarcoma. (D) The top ten organs with a high incidence of lymphoma. 30 of $p53^{-/-}$ homozygous mice were used in this experiment.

The uniform tumorigenesis of this model may result from its homogeneous genetic background. Before the establishment of the B6 ES cell line in 2007 [19] and application of the CRISPR/Cas9 system in mammalian cells [20], most genetically modified animal models were developed by targeting ES cell lines derived from 129/Sv mice, which require several generations of backcrossing with C57BL/6 to modify the genetic background. However, these mouse models still have a mixed background even after 20 generations of backcrossing. In the present study, the $p53$ deletion model using a C57BL/6 derived ES cell line has a pure genetic background. Therefore, mice with the same genetic background developed uniform malignant lymphoma as well as retinal degeneration (Supplementary Figure 3).

According to the somatic mutation theory, genetics and the environment (carcinogens), as well as their interactions, can drive tumorigenesis [21–23]. $p53$ is a
crucial tumour suppressor gene and plays important role in physiological processes [24, 25]. Furthermore, p53 gene mutation or deletion promotes tumorigenesis in humans and animal models [18, 22, 26, 27]. The potential for carcinogens to induce or accelerate tumour genesis has also been reported intensively [8, 28, 29]. Different strategies have been used to develop lymphoma models, such as humanized mice, xenografting, [3, 4] or others [30, 31] to mimic the effect of genetic and environmental factors on tumorigenesis. Here, we established a lymphoma model with 4 months of latent period of lymphoma instead of over 6 months.

Parameters that affect tumorigenesis in p53-deficient mice have been widely described, such as genetic background, status of the p53 gene (homozygous or heterozygous) [6, 12, 14]. According to a previous report, p53 gene deletion models on a B6 background were susceptible to lymphoma. Various mouse strains, including D3 [14], BALB/c [7], 129/Sv [6, 12], and C57BL/6 (this work) have been used for p53 gene deletion models, all of which exhibited diverse tumour spectra and prominent tumour types. Table 4 shows that the top three spontaneous tumours in D3-p53+/– mice were osteosarcoma, lymphoma, and fibrosarcoma [14]. The main tumour types in BALB/c background P53+ mice were mammary carcinoma, lymphoma, and hemangiosarcoma. Because the early onset of mammary carcinoma is the most common cancer in women with Li-Fraumeni syndrome, this model was considered a Li-Fraumeni syndrome model [7]. In 129/Sv mice, the major tumours were osteosarcomas and lymphomas. However, only low lymphoma frequencies (from 22% to 25%) were observed in these three mouse models. As expected, given Knudson’s two-hit hypothesis [13], the profile of p53 gene deletion homozygous mice was quite different from heterozygotes; spontaneous lymphoma was the prominent tumour type, with frequencies up to 65% in BALB/c mice [7] and 71% in D3 [14] mice. Interestingly, we observed the frequency of spontaneous lymphoma was 47% in 129/Sv-p53+/– mice, 75% in C57BL/6 mice, and 25% in 129/Sv mixed-background mice increasing to 65%–75% (Table 4), while in mice with 100% C57BL/6 background, the frequency of lymphoma was 93.3% (Figure 2). By linear regression, we demonstrated that frequency of lymphoma was positively correlated with the percentage of C57BL/6 background (R² = 0.85, Figure 8). However, when C57BL/6-p53

**Figure 3:** Lymphoma occurrence in p53 deficient heterozygous mice induced by 37.5 mg/kg MNU. (A) Survival curve of p53+ mice administered 37.5 mg/kg MNU. (B) The tumour profile and frequency of p53+ and wild-type mice administered MNU. Only lymphomas were observed in both mouse strains. p53+ mice were more susceptible to MNU than wild type mice. (C) The relative tumour frequency of lymphoma, adenoma, rhabdosarcoma, and leiomyosarcoma. (D) The malignant lymphoma frequency in various organs. 17 p53+ and 20 wild type mice were used in this experiment.
heterogeneous mice were induced with 75 mg/kg of MNU, the frequency of lymphoma increased to 100% (Figure 4) in contrast with 85% in 129/Sv mice and B6 mixed-background mice [8]. Previous studies represented that the genetic background of mice may alter tumor development, but tumorigenesis is not strain-specific [12, 32]. Combined with our data and clinical observations [33], we hypothesise that tumour genesis is strain specific, and B6 background mice are lymphomagenesis prone, but how the B6 genetic background affects the tumour profile or frequency is still unknown.

Lymphomas in this model were of the T cell lineage because they were CD3, CD4, CD8 positive, and CD20 and CD68 negative (Figure 6, Supplementary Figure1). The present model is similar to the clinical T-cell lymphoma type with the worst prognosis in human patient [34]. Therefore, this model might be a useful tool for studying the mechanisms of lymphomagenesis and drug selection for treatment.

**MATERIALS AND METHODS**

**Derivation of C57BL/6 ES cells**

C57BL/6 mice were maintained in the 12-hour light/12-hour dark cycle. To obtain blastocysts, female mice were induced to superovulate and blastocysts were flushed out from uterine horns of 3.5 dpc pregnant females. Blastocysts were cultured for 5–6 days on feeder cells in 12-well plates, and the ES cell medium was changed every 1–2 days. The size of ICMs increased markedly in culture. They consisted of a central mass of stem cells and peripheral primitive endoderm-like cells. They were picked up with a mouth-controlled micropipette into a 48-well plate and then digested by 0.1% collagenase for 10–15 min followed by 0.25% trypsin for 2–5 min. The digested ICMs were transferred onto new feeder cells for continuous cultures until ES cell colonies were observed.

**Mouse ES cell culture**

C57BL/6 ES cells were cultured at 37°C in a humidified 5% CO₂ incubator. They were routinely maintained on mitotically inactivated MEFs with Knockout DMEM medium (Gibco) supplemented with 15% FBS (ExCell), 1% MEM NEAA (Gibco), 1% L-glutamine (Gibco), 0.1% β-Mercaptoethanol (Gibco) and 1% CHO-LiF. Mouse ES cells were passaged every 2–3 days. For routine passaging, mouse ES cells were

---

**Figure 4:** Lymphoma occurrence in **p53** deficient heterozygous mice induced by 75 mg/kg MNU. (A) Survival curve of **p53**+/− mice administered 75 mg/kg MNU. Most animals died between 13–17 weeks after MNU administration. (B) The tumour profile and frequency of **p53**+/− mice. Lymphoma and adenoma were observed. Notably, the occurrence rate of lymphoma was 100%. (C) Relative tumour frequency of lymphoma, adenoma, rhabdosarcoma, and leiomyosarcoma. (D) The malignant lymphoma frequency in various organs. 14 **p53**−/− mice were used in this experiment.
detached by pipetting and collected by centrifugation. Then, 0.05% trypsin was added to dissociate the cell aggregates into single cells. Passaging cells in this way avoids a carryover of feeders, which adversely affects mouse ES cell growth.

**Karyotype analysis of ES cell lines**

For karyotyping, mouse ES cells were plated onto 6-well plates at a density of $1 \times 10^6$ cells per well. One day after plating, 0.5 mg/ml colcemid (Sigma) was added to the culture and incubated for 50 min at 37°C water bath. The mouse ES cells were then trypsinised, fixed with methanol-glacial acetic acid (3:1) solution, and spread onto glass-slides. Chromosome G-binding was analysed for karyotypes by microscopy.

**Generation of $p53$ gene knockout mice**

We constructed the mouse $p53$ gene-targeting vector using a PGK promoter to drive the expression of a neomycin selection cassette (Neo). The targeting vector was introduced into C57BL/6 mouse ES cells by electroporation. After homologous recombination, the targeting vector replaced the $p53$ gene from exon 2 to 5. Neomycin resistant ES cell colonies were selected, screened by PCR, and injected into 151 wild-type BALB/c blastocysts. ES-cell-injected blastocysts were then transferred to 14 pseudo-pregnant mice and 8 chimeric mice were produced. The male chimera mice were crossed with wild-type C57BL/6 female mice to generate heterozygous $p53$ gene knockout mice.

**Southern blot analysis**

Genomic DNA was extracted from mouse-tail biopsies and used for Southern blot analysis. After digestion with EcoRI (for the 5’ probe), the genomic DNA samples were analysed by gel electrophoresis with a 1% agarose gel. After electrophoresis, the gel was denatured, neutralized, and blotted by capillary transfer on a nylon membrane. The DNA membrane was fixed and hybridized with digoxigenin-labelled Southern blot hybridization probes according to the manufacturer’s instructions (Roche).

**Mice genotyping and RNA analysis**

Tail genomic DNA was isolated using a Tissue Genomic DNA Extraction Kit (Generay, Shanghai, China) and then subjected to PCR to verify deletion of

the p53 gene. Genomic DNA of p53 deficient mice and wild-type mice were amplified with primer sets 1 (P53-WT-F, AGTTCTGCCACGTGGTTGGT; P53-WT-R, GTCTCCTGGCTCAGAGGGAG) or 2 (P53-WT-F, AGTTCTGCCACGTGGTTGGT; P53-Neo-R, CAGAGGCCACTTGTGTAGCG), with expected PCR products of 281 bp or 441 bp for wild-type and homozygous mutations, respectively. For the heterozygous mutation, both bands were visible.

Tissues were dissected and immediately immersed into RNA later stabilization reagent (Invitrogen) and stored at −80°C. Total RNA was extracted from individual tissues using TRIzol (Invitrogen) and quantified using a spectrophotometer at OD 260 nm. Random hexamers were used to prime reverse-transcription reactions with Superscript III (Invitrogen). Real-time quantitative PCR was performed using an ABI 7300 Real Time PCR System with SYBR green I reagent (Takara Bio Inc.). The primer sets for Q-PCR analysis were p53 F1, 5'-CCCCTGTACATTT TTGGCCCT-3' and p53 R1, 5'-AGCTGGCAGAATAGCTTATTGAG-3; F2, 5'-CGGAACATCTCGAAGCGTTTA-3' and R2, 5'-CGGAACATCTCGAAGCGTTTA-3.

**Spontaneous malignant lymphoma in p53−/− mice**

Thirty p53−/− mice were maintained for the observation of spontaneous tumours. All mice were observed and palpated daily, and the clinical signs were recorded. Moribund mice were euthanized and anatomicized immediately. Dead mice were necropsied immediately or kept at a low temperature and necropsied the next day. Tissues examined for histopathology examination included the adrenal gland, aorta, brain (forebrain, midbrain, and hindbrain), cecum,

f) nd: not determined.

colon, duodenum, epididymis, oesophagus, eyes, femur with bone marrow, Harderian glands, heart, ileum, jejunum, gall bladder, kidneys, liver, lung with bronchi, lymph nodes (mesenteric and mandibular), mammary gland (female only), optic nerves, ovaries, oviduct, pancreas, pituitary prostate, rectum, salivary gland, sciatic nerve, seminal vesicles, skeletal muscle(thigh), skin and subcutis, spinal cord (cervical, thoracic, and lumbar), spleen, sternum with bone marrow, stomach, testis, thymus, thyroid and parathyroid glands, tongue, trachea, tumours/masses, urinary bladder, uterus with cervix, vagina, and gross lesions.

**MNU induced malignant lymphoma in p53+/− mice**

Thirty C57BL/6 wild-type mice and fifty p53+/− deficient mice (almost half male and half female) were grouped and administered 37.5 or 75 mg/kg MNU or citrate buffer as a control. MNU was dissolved in citrate buffered saline and adjusted to pH 4.5 before a single dose administration to animals by intraperitoneal injection on Day 1 followed by a six-month observation period. All mice were observed twice daily, and clinical signs were recorded once daily. Body weights were recorded at least once before treatment and weekly following treatment. Beginning 12 weeks after treatment, mice were palpated weekly until the end of the study. All surviving animals were sacrificed and necropsied at the end of 26 weeks.

**Immunohistochemical analysis and flow cytometry**

Mouse tissues were fixed in 10% neutral buffered formalin, embedded in paraffin, and sectioned (5 μm).
For histopathological examination, tissue sections were stained with haematoxylin and eosin.

Immunohistochemical stains were applied to formalin-fixed, paraffin-embedded sections of the thymus from five animals per gender with thymic malignant lymphoma in the MNU-treated group and to thymic sections from two control males and two control females. Antibodies directed against CD3 (T-lymphocyte marker), CD20 (B-lymphocyte marker), and CD68 (macrophage marker) were used to classify the lineage of the neoplastic cells in the thymus. Thymic malignant lymphoma or thymic sections for CD3, CD20, and CD68 staining were pretreated by incubating at 96°C in Citra buffer (Zhongshan Golden Bridge Biocompany, Beijing, China) at pH 6 in a microwave oven for 10 minutes. Sections for CD3 staining were incubated with anti-CD3 antibody (clone LN10, Zhongshan Golden Bridge Biocompany, Beijing, China) at a 1:150 dilution overnight at 4°C after blocking with normal goat serum for 60 minutes at 37°C. The sections for CD20 staining were incubated with anti-CD20 antibody (clone EP7, Zhongshan Golden Bridge Biocompany, Beijing, China) at a dilution of 1:200 overnight at 4°C after blocking with normal goat serum for 60 minutes at 37°C. The sections for CD68 staining

![Figure 7: Dynamics of body weight in male and female mice treated with or without 75 mg/kg MNU. Troughs of body weight of mice treated with MNU were observed at 2–3 weeks and 12–13 weeks as indicated by arrows. The second trough is consistent with the moribund or death of animals. Data are presented as the mean ± standard deviation (n = 10 per group).](image)

![Figure 8: Relationship between rate of lymphoma occurrence and genetic background. Genetic background is labelled in the panel. R² represents the coefficient of determination, original data and references listed in Table 4.](image)
were incubated with anti-CD68 antibody (clone PG-M1, Zhongshan Golden Bridge Biocompany, Beijing, China) at a dilution of 1:200 overnight at 4°C after blocking with normal goat serum for 60 minutes at 37°C. CD3, CD20, and CD68 immunoreactivity were all detected using a biotinylated rabbit anti-rat secondary antibody followed by an avidin-biotin-horseradish peroxidase complex and visualized with diaminobenzidine. All immunohistochemical sections were counterstained with haematoxylin, dehydrated in graded concentrations of ethanol, and coverslipped routinely using permanent mounting medium.

To detect CD4, CD8 positive cells, enlarged thymus and spleen of \( p53^-^- \) mice over six months (according to previous experiments, usually indicating lymphoma has occurred) were collected and using BD FACS Calibur (Becton Dickinson, Franklin Lakes, NJ, USA) to perform multicolour cytometric analysis. The erythrocytes in the thymus and spleen cells were depleted by Lysing solution (BD Phar Mingen, San Diego, CA, USA). Anti-mouse CD4 and CD8 monoclonal antibodies were purchased from BD Phar Mingen.

Statistical analysis

The Fisher exact test was used to analyse tumour incidence data and the Fisher least significant difference test was used to analyse body and organ weights. The statistical analysis result of haematology data was shown as the mean ± standard deviation (SD) or One-Way Analysis of Variance (ANOVA). SPSS 19.0 software was used to analyse the results. Dunnett’s parametric test was used for multiple comparisons between groups. \( P < 0.05 \) was considered statistically significant. \( P < 0.01 \) was considered highly significant.

Abbreviations

MNU: N-methyl-N-nitrosourea. SD: standard deviation. WBC: white blood cell. NEU: neutrophil count. LYM: lymphocyte count. MONO: Monocytes count. EOS: Eosinophil count. BASO: basophile count.
