A thermodynamically consistent model of bone rotary remodeling: a 2D study

M. Martin, T. Lemaire, G. Haïat, P. Pivonka and V. Sansalone

1. Introduction

Bone remodeling characterizes the lifelong turnover and adaptation of bone tissue to its mechanical and biochemical environment. This phenomenon is of major importance, as it governs healing as well as osseointegration around implants (Haïat et al. 2014).

Several scales and physics are involved in bone remodeling. Indeed, changes of the mechanical environment of bone at the organ scale lead to apposition and resorption of bone material at the microstructural scale which, in turn, result in an evolution of the mechanical properties of bone tissue, at the tissue scale. Moreover, biochemical stimuli can also trigger bone remodeling.

In this work, we present a thermodynamically consistent framework for describing the evolution of bone elastic properties at the tissue scale. Such an approach allows to consider not only mechanics, but also phenomena related to biological activity. In particular, we focus on the stress-driven rotation of the principal axes of the elastic tensor of bone. Rotation of bone material axes describes, at the tissue scale, the reorientation of bone microstructure induced by the macroscopic loading.

2. Methods

In the present study, bone tissue is described as an orthotropic elastic medium whose elastic properties evolve in time according to the mechanical environment (DiCarlo et al. 2006). The remodeling process is represented as the rotation of the bone microstructure which is linked to the macroscopic loading.

The complete motion of a material point of such a medium requires a two-layer description: On the one side, its position in space (gross motion); On the other side, the rotation of its material axes. A generalized virtual power principle, encompassing the virtual power expended by velocities related to both the gross motion and the rotation of the material axes, leads to the continuum balance laws. A constitutive theory is then built on the definition of a strain energy density depending on the elastic strain and of the orientation of the material axes. Finally, the formulation of the dissipation principle leads to a remodeling evolution law giving an explicit relationship coupling the dissipation related to the remodeling (the fourth-order tensor \(D\)), the stress and strain tensors (the second-order tensors \(S\) and \(E\), respectively), the rotation of the material axes (the second-order rotation tensor \(R\)) and its time derivative (\(\dot{R}\)):

\[
D(\dot{RR^T}) = [S, E],
\]

where \([S, E] = SE - ES\). Remodeling equilibrium is achieved when material properties no longer evolve, corresponding to a stationary state of the rotation. This condition corresponds to an equilibrium at the macroscopic scale, which does not account for the modeling and remodeling cell activity at the lower scale.

It is worth noting that this model predicts the principal axes of the strain and stress tensors to be locally collinear at the remodeling equilibrium (Sansalone et al. 2011). Thus, a physically sound condition for remodeling equilibrium (Cowin 1986) is recovered without any ad hoc assumption.

3. Results and discussion

The model was tested on simple 2D toy models.

Firstly, the model was applied to a macroscopic unit of bone tissue to follow the evolution of the local orientation of the material as well as strain energy until equilibrium. When constant strain conditions are applied, the medium tends to minimize the strain energy to reach equilibrium.
future works. Eventually, it should be mentioned that our model is only able to describe the global remodeling taking place in a medium. However, bone remodeling is a lifelong process and remodeling equilibrium results from the balance of bone resorption and apposition. So far, our model can only describe the net result of these two biological processes and is not able to distinguish between such a ‘dynamical’ equilibrium state – where the two biological processes are balanced – and the complete absence of remodeling – where the two biological processes are simply stopped. In order to distinguish between these two very different situations, a finer description of the individual biological processes leading to bone remodeling should be introduced, e.g. as proposed in (DiCarlo et al. 2009) in the scope of growing aneurysms.
