We studied the recollision dynamics between the electrons and D$_2^+$ ions following the tunneling ionization of D$_2$ molecules in an intense short pulse laser field. The returning electron collisionally excites the D$_2^+$ ion to excited electronic states from there D$_2^+$ can dissociate or be further ionized by the laser field, resulting in D$^+ +$ D or D$^+$ + D$^+$, respectively. We modeled the fragmentation dynamics and calculated the resulting kinetic energy spectrum of D$^+$ to compare with recent experiments. Since the recollision time is locked to the tunneling ionization time which occurs only within fraction of an optical cycle, the peaks in the D$^+$ kinetic energy spectra provides a measure of the time when the recollision occurs. This collision dynamics forms the basis of the molecular clock where the clock can be read with attosecond precision, as first proposed by Corkum and coworkers. By analyzing each of the elementary processes leading to the fragmentation quantitatively, we identified how the molecular clock is to be read from the measured kinetic energy spectra of D$^+$ and what laser parameters be used in order to measure the clock more accurately.

I. INTRODUCTION

The fragmentation and ionization of D$_2$ by intense optical laser fields has been an active area of theoretical and experimental studies during the past decades. In most of these experiments it was assumed that the D$_2$ molecule is ionized in the early phase of the laser field producing D$_2^+$ ion which is subsequently ionized by the laser. Mechanisms for the ionization of D$_2^+$ ion include bond softening (SO), charge resonance enhanced ionization (CREI), in addition to direct ionization by the laser field. The dissociation and ionization of D$_2^+$ in the laser field result in D$^+$ + D or D$^+$ + D$^+$, with characteristic kinetic energies reflecting the internuclear separation of the breakup of D$_2^+$ at the time when it is excited or ionized. Thus bond softening and CREI, which produce distinct peaks in the D$^+$ ion kinetic energy spectra have been observed experimentally and predicted theoretically. These peaks can be understood without reference to the ionization of D$_2$ itself initially, i.e., the ionization of D$_2$ and D$_2^+$ can be treated as two independent events. However, recent experiments pointed out a new group of peaks in the D$^+$ ion spectra at the higher energy (about 5 eV to 10 eV per ion) which has now been attributed to the rescattering process. In the rescattering process, the electron which is released by tunneling ionization is driven back by the laser field to collide with the residual D$_2^+$ ion to ionize it or to excite it. If the D$_2^+$ ion is excited, it can dissociate directly or be further ionized by the laser. In both cases, the D$^+$ ion will have kinetic energy (the reflection principle) characteristic of the internuclear separation where the ionization occurs. This paper is to examine all the elementary processes that lead to the dissociation or ionization of D$_2$ molecules in a laser field. Starting with the tunneling ionization of D$_2$, we address the following issues: (1) Calculation of the ionization rates of D$_2$ from its equilibrium distance using the molecular tunneling ionization (MO-ADK) theory; (2) The classical trajectory of the ionized electron in the laser field and the Coulomb field of the D$_2^+$ ion, with initial longitudinal and transverse velocity distributions following the description of the ADK theory; (3) The free propagation and spreading of the nuclear wave packet after the tunneling ionization of D$_2$ from its equilibrium distance; (4) Semi-empirical formulae for electron impact excitation cross sections of D$_2^+$ from the $\sigma_g$ ground state to the first few excited electronic states, in particular, the first $\sigma_u$ and $\pi_u$ states. These cross sections have to be evaluated at all values of internuclear separations and for different alignment angles of D$_2^+$ with respect to the laser polarization direction; (5) Evaluation of tunneling ionization rates of D$_2^+$ from the excited $\sigma_u$ and $\pi_u$ states at each internuclear separation; (6) Follow the time evolution of dissociation and ionization dynamics to extract the kinetic energy spectra of the fragmentation products. While rates or cross sections for each of these elementary processes have been formulated, in the full calculation we only consider D$_2$ initially aligned perpendicular to the direction of the laser polarization. In Sec. the resulting kinetic energy spectra of D$^+$ are compared to the experiment of Niikura et al.

where $D^+$ ions were detected without knowing whether the other fragmentation product is a $D$ or a $D^+$. In contradiction to the conclusion of this work where the main peak in the $D^+$ kinetic energy spectrum was attributed to the dissociation of $D^+_2$ following excitation to the $\sigma_u$ electronic state, we conclude from our calculation that the main peak is due to the further ionization of the excited $D^+_2$ by the laser. This has the consequence that the molecular clock we read is at a different time from the one read in Niikura et al. [4]. We further analyzed the contributions of the total kinetic energy spectra of $D^+$ resulting from the different excited electronic states, from dissociation or ionization, and from rescattering at the first return, the third return, or higher returns. The simulated $D^+$ kinetic energy spectra from ionization also were compared to the recent experiment of Alnaser et al. [20]. From our analysis, we conclude that the fragmentation of $D_2$ can be used as a molecular clock based on the rescattering dynamics. The clock can be read more accurately if the laser pulse is chosen at the lower intensity and with a shorter duration. With such a clock, the time duration can be read with an accuracy of fraction of a femtosecond without the attosecond laser pulses. Equivalently this means that the distance between the two nuclei can be read with an accuracy of fractions of an Angstrom. This can be achieved experimentally by comparing kinetic energy spectra for experiments carried out at different mean laser wavelengths, or by comparing the kinetic energy spectra of $D^+$ and $H^+$ from the fragmentation of $D_2$ and $H_2$, respectively, in the same laser pulse. We finish this paper with a summary and conclusion in Sec. [LV].

II. THEORETICAL MODEL

A. The elementary processes

The schematic of the physical processes leading to the fragmentation of $D^+_2$ ion following the ionization of $D_2$ molecule in an intense laser pulse is depicted in Fig. 1. The $D_2$ molecule is first ionized at $t_0$ near the peak of the laser pulse, releasing an electron into the oscillating laser field. At $t_1$, the electron is driven back to the molecular ion, to excite the other electron in the ion to one of the higher excited electronic states, or to ionize it. We will be dealing with peak laser intensities such that the returning electron does not have enough energy to ionize $D^+_2$. In the meanwhile, the nuclear wave packet propagates from its mean internuclear distance $R_0=1.4$ a.u. at $t_0$ to $R_1=1.6$ a.u. at $t_1$. Thus the electron impact excitation probabilities of the molecular ion by the returning electron have to be calculated for $D^+_2$ with a vibrational distribution $\chi^2(R,t)$. This distribution is indicated in the second row of Fig. 1. Once the $D^+_2$ is in the excited state, represented by the curve labelled $\sigma_u$ and $\pi_u$ in Fig. 1, the $D^+_2$ can dissociate directly to $D^++D$, or it can be further ionized by the laser at $t'_1$ when the electric field of the laser returns to its peak value. If the $D^+_2$ is ionized at $t'_1$, then it will fragment by Coulomb explosion to produce $D^++D^+$ ions. The total released kinetic energy for such a “two-step” process can be calculated.

The rescattering does not have to occur only at the first return time $t_1$. Due to the attractive field from the molecular ion, the released electron can return to collide with the molecular ion at later times, i.e., after more than one optical cycle, following the initial ionization. For example, the return can occur at $t_2$ and $t_3$, in the second optical cycle, or at $t_4$ and $t_5$, in the third optical cycle, and so on. At these later times excitation and ionization occur at larger internuclear separations, thus the kinetic energies of the fragmented $D^+$ ion are smaller. In general the returning probabilities become small after three optical cycles. Following the general convention we call $t_2$ the second return and $t_3$ the third return, etc...

An important feature of the elementary processes described above is that the rescattering times $t_i$ and the subsequent tunneling ionization time $t'_i$ are relatively well locked to the clock $t_0$ of the initial ionization of $D_2$. Since tunneling ionization occurs only near the peak of the
Similarly, $t_i$ and $t'_i$ are also restricted to within sub-fs accuracy. These precise clocks in turn define precise internuclear separations. For laser pulses with mean wavelength at 800 nm, the mean internuclear distances $R_i$ for $t_i$ (i=1,3,5,7) are shown in Table I for H$_2$ and D$_2$. Note that at $t_7$, the center of the vibrational wave packet for H$_2^+$ has already bounces back from the outer turning point, but not so for D$_2^+$. A classical estimate shows that it takes 8.5 fs to reach its outer turning point. During these later times, the wave packet spreads significantly. The clock or the mean internuclear separation can be read from the kinetic energy peaks for different laser parameters. The electron impact excitation probabilities and rates are needed to change the clock but will change the mean internuclear distances.

To read the clock from the measured kinetic energy of the fragmented ion, however, there are a number of factors that make the clock “fuzzy”. First, the initial tunneling ionization occurs over an interval of about 0.3 fs near the peak of the laser field. The initial vibrational wave packet, taken to be the ground vibrational wavefunction of D$_2$, according to the Frank-Condon principle, has a width of 0.2 nm. This vibrational wave packet will broaden as it expands to larger internuclear separations. The electron impact excitation probabilities and the MO-ADK rates also depend on internuclear separations. These factors would reduce the precision of the clock such that distinct peaks in the kinetic energy distribution of the fragmented ions are not as clearly separated. We model the rescattering process to check how accurately the molecular clock can be read from the kinetic energy spectra of the fragmented ions for different laser parameters.

We now describe the models used for calculating the rates and probabilities for each elementary process.

### B. Tunneling ionization rates for molecules

We first discuss how the ionization rates of D$_2$ and D$_2^+$ in the laser fields are calculated. From the rescattering model above, we need the ionization rates for D$_2$ from the ground state, and for D$_2^+$ from the excited $\sigma_u$ and $\pi_u$ states over the whole range of $R$. The rates are needed for different alignment of the molecules as well.

We calculated the tunneling ionization rates using the recently developed MO-ADK model [25]. It was obtained by extending the widely used ADK [27, 28] theory for atoms in a laser field to molecules. In the MO-ADK theory the ionization rates are given in semi-analytical expressions. For a diatomic molecule in a parallel static electric field, the ionization rate for a valence electron is given by

$$W_m(F) = \frac{B^2(m)}{2|m|! |m|! \kappa^{2|m|/\kappa - 1}} \times \left(\frac{2\kappa^3}{F}\right)^{2\kappa^3/\kappa - |m| - 1} e^{-2\kappa^3/3F},$$

with

$$B(m) = \sum_l C_{lm} (-1)^m \sqrt{\frac{(2l + 1)(l + |m|)!}{2l - |m|!}}.$$  

Atomic units are used unless otherwise indicated. In Eq. (1), $\kappa$ is related to the ionization energy $I_p$ by $\kappa = \sqrt{2I_p}$, $l$ is the orbital angular momentum of the valence electron, $m$ is its projection along the internuclear axis, $Z_e$ is the effective charge seen by the valence electron in the asymptotic region and $F$ is the field strength. In Eq. (2), the parameters $C_{lm}$ are determined from the valence electron wave function of the molecule in the asymptotic region. The laser peak power will be given in units of $I_0 = 10^{14}$ W/cm$^2$ and the mean wavelength is 800 nm. If the molecule is aligned at an angle $\theta$ with respect to the laser polarization direction, the ionization rate is given by

$$W_m(F, \theta) = \sum_{m'} W_{m'}(F),$$

where $W_{m'}$ is given in Eq. (1) except that

$$B(m') = \sum_l C_{lm} D_{m',m}(0, \theta, 0) \times (-1)^{m'} \sqrt{\frac{(2l + 1)(l + |m'|)!}{2l - |m'|!}},$$

where the $D$-function expresses the rotation of the electronic wave function from the direction of the molecular axis to the laser polarization direction. In the MO-ADK model, Eq. (1) reduces to the traditional ADK model for atoms if $l$ is taken to be the orbital angular momentum quantum number of the valence electron. For diatomic molecules, the summation over $l$ is a consequence of expanding the two-center electronic wave function in terms of single-center atomic orbitals. The coefficients $C_{lm}$ are functions of $R$ and depend on the electronic states of the molecule.

For D$_2$ at the equilibrium internuclear separation, the parameters $C_{lm}$ have been calculated by Tong et al. [25].

| return | time (fs) | $< R >$ (a.u.) |
|--------|----------|--------------|
| $t_1$  | 1.9      | 1.8, 1.6     |
| $t_3$  | 4.3      | 2.5, 2.1     |
| $t_5$  | 7.0      | 3.0, 2.6     |
| $t_7$  | 9.6      | 3.2, 3.0     |
Within the range of its ground vibrational wavefunction, it was found that the MO-ADK rates depend weakly on R. It was also found that the major component of B(n=0) in Eq. (2) is l=0, for D₂, thus the MO-ADK rates for D₂ depend weakly on the alignment of the molecule. The accuracy of the MO-ADK rates for D₂ at the equilibrium distance had been checked previously and found to be in good agreement with the result from \textit{ab initio} calculations \cite{29}.

We next consider the ionization of D₂⁺ in a laser field. Since the ionization rate depends sensitively on the ionization potential, in Fig. 2 we show the electronic binding energies Eᵢ(R) at each R of the first four electronic states of D₂⁺. The negative of the electronic binding energy is the ionization potential. The total potential energy of each electronic state is Uᵢ(R) = Eᵢ(R) + 1/R. For peak laser intensity in the range of 0.5-5 I₀, estimate based on the simple ADK theory or the more complete MO-ADK theory shows that D₂⁺ in the σg state will not be ionized by the laser except for R greater than about 5 a.u., while for πu and πg states the D₂⁺ will be readily ionized because of the much smaller ionization potentials. Thus we need to calculate only the MO-ADK rates of D₂⁺ in the σu state as a function of the internuclear distance R.

In Fig. 3 we show the calculated MO-ADK tunneling ionization rates at F=0.06 a.u. for the σu electronic state of D₂⁺, for R in the range of 1-6 a.u. and for alignment angle θ=0° and 90°. At θ=0°, the MO-ADK rates have been checked against the “exact” static tunneling ionization rates calculated using the complex rotation method in the two-center system \cite{30}. The MO-ADK rates tend to be somewhat higher, especially at small and large R region. For R greater than 6.0 the σu ionization energy is already very close to the ionization energy of atomic H, thus the ADK ionization rates of H(1s) are used for \( R > 6.0 \). In the actual calculation, the coefficients \( C_{lm} \) are obtained for each R such that the MO-ADK rates can be readily calculated for any field strength, and any alignment angle of the molecule using Eq. 3.

### C. The rescattering model

Following the initial ionization of D₂⁺, a correlated electron wave packet and a vibrational wave packet are created at \( t_0 \). The initial vibrational wave packet is taken to be the ground vibrational wavefunction of D₂, assuming that the ionization process is fast and the Frank-Condon principle is valid. Due to the heavy mass of the nuclei, the vibrational motion is not modified by the subsequent laser field. The time evolution of the vibrational wave packet is thus described by

\[
\chi(R, t) = \sum_v C_v \chi_v(R) e^{-i \varepsilon_v t}, \tag{5}
\]

\[
C_v = \int \chi_g(R) \chi_v(R) dR. \tag{6}
\]

Here \( \{ \chi_v(R) \} \) and \( \{ \varepsilon_v \} \) are the vibrational wavefunction and vibrational energy of D₂⁺ in the σg ground electronic state, respectively, and \( \chi_g(R) \) is the the ground vibrational wave function of D₂.

The rescattering model for describing the motion of the ionized electron in the subsequent laser field is modeled similar to the method used by Yudin and Ivanov \cite{22, 23} for He. The ionized electron is treated classically, under the combined force from the laser field and the residual Coulomb interaction from the D₂⁺ ion. For simplicity, the latter is approximated by an effective charge \( Z_e = +1 \) at the midpoint of the internuclear axis. To calculate the trajectory of the ionized electron, we solve the equation of motion (Newton’s second law), with the initial condition...
that the ionized electron is at \((x,y,z) = (0,0,z_0)\) where \(z_0\) is
the tunnelling position from the combined potential of the Coulomb field and the static electric field. The initial velocity \(\mathbf{v}\) is assumed to have a distribution from the ADK model,

\[
g(\mathbf{v}) \propto e^{-v^2 \kappa/F}.
\]

In this model, the tunneled electron is ejected isotropically with a Gaussian distribution in velocity, i.e., we consider the ejected electron have initial velocity in both the transverse and the longitudinal directions. For each initial time \(t_0\) or phase \(\phi_0\) that the ionized electron was born, the classical equation of motion was solved to obtain the trajectory. The distance of the electron from the center of \(\text{D}_2^+\) ion is monitored for over seven optical cycles for longer pulses or till the end of the laser pulse if the pulse is shorter. The distance of the electron from the ion and the time when this occurs for each trajectory are recorded. From these data, the impact parameter \(b\) and the collision energy \(T\) of the corresponding electron-ion impact (no laser field) excitation or ionization are obtained.

Figure 4 shows the probability distribution of finding the returning electron with kinetic energy \(T\) measured in the asymptotic region for a laser with peak intensity at 1.5 \(I_0\) \((I_0 = 10^{14} \text{ W/cm}^2)\) and pulse length of 40 fs obtained from the simulation.

In our calculations we have accounted for rescattering up to seven optical cycles for the long laser pulses.

**D. Electron impact excitation and ionization probabilities**

For each impact parameter \(b\) and kinetic energy \(T\) of the returning electron, we need to calculate the electron impact excitation and ionization cross sections of \(\text{D}_2^+\) at each internuclear separation \(R\). Different from the \(\text{He}^+\) case, there are few experimental or theoretical data available for \(\text{D}_2^+\). Thus we have to generate the cross sections needed semi-empirically. For each total cross section \(\sigma(T)\) at kinetic energy \(T\), we assume that the probability for excitation or ionization at impact parameter \(b\) is given by

\[
P_m(b,T) = \sigma(T) \frac{e^{-b^2/a_o^2}}{\pi a_o^2},
\]

\[
a_o = \sqrt{2/\Delta E},
\]

where \(T = v^2/2\) and \(\Delta E\) is the excitation or ionization energy. Here, the \(b\)-dependence is taken to be the Gaussian form. For the rescattering in \(\text{He}\), Yudin and Ivanov [22] have checked different forms of \(b\)-dependence and concluded that the results are rather insensitive to the precise functional form used.

For electron impact ionization cross section, we employ the empirical formula

\[
\sigma_i(T,\Delta E) = \frac{\pi}{\Delta E^2} e^{1.5\sqrt{(\Delta E-0.5)/T}} f(T/\Delta E)
\]

\[
f(x) = (A \ln x + B(1-\frac{1}{x}) - C \ln x \frac{1}{x^2}).
\]

where \(\Delta E\) is the ionization energy. By fitting this formula to the accurate theoretical \(\text{H}(1s)\) ionization cross
section 31 we obtained $A = 0.7213$, $B=-0.302$, $C=0.225$. The fitted formula, when applied to $\text{He}^+$, gives ionization cross sections in good agreement with the theoretical results of Bray 31 for $\text{He}^+$ as well. For $D_2^+$ at the equilibrium distance this formula also reproduces the recommended ionization cross section from NIST 32. In this semi-empirical model, the molecular ion is treated as a point particle, thus the ionization cross section is independent of the alignment of the $D_2^+$ ion.

For the excitation process, it is clear from Fig. 2 that $\sigma_u$ and $\pi_u$ states will be the dominant channels populated via electron impact excitation from the ground $\sigma_g$ state since they have the lowest excitation energies. There are no theoretical or experimental data available for such cross sections as functions of internuclear separations. Thus we will employ semi-empirical fitting procedure as well. We assume that the excitation cross section again can be fitted in the form of Eqs (10) and (11) as in ionization, except that $\Delta E$ now is the excitation energy and the number 0.5 in Eq (11) should be replaced by the excitation energy of the corresponding state in atomic hydrogen. From the tabulated $\text{H}(1s) \rightarrow \text{H}(2p)$ excitation cross section in Bray 31, we obtained $A = 0.7638$, $B=-1.1759$, $C=-0.6706$. The formula was further tested by comparing the predicted excitation cross section with the calculated one for $e^- + \text{He}^+(1s) \rightarrow e^- + \text{He}^+(2p)$. From the total $1s \rightarrow 2p$ excitation cross section, we can further distinguish excitation cross section to $2p_0$ or $2p_1$, with the direction of the incident electron beam as the quantization axis. The relative $2p_0$ and $2p_1$ cross sections can be calculated theoretically or experimentally from polarization or correlation measurements. (Note: $2p_{-1}$ cross section is identical to $2p_1$ cross section by symmetry.) In Fig. 5 we show the relative cross sections of $2p_0$ to $2p_1$ from the calculation of Bray 33 for $\text{H}$, plotted against scaled energy (with respect to the excitation energy). On the same graph we display the same ratio for the excitation of $\text{He}$ from $1s^2$ to $1s2p^1P_0$ from the experiment of Merabet et al. 34. It appears that the both $\text{H}$ and $\text{He}$ data fall on the same curve when the collision energy is scaled with respect to the excitation energy. We fit the $2p_0$ to $2p_1$ cross section ratio by

$$r(x) = \frac{\sigma_0}{\sigma_1} = \frac{8.2\sqrt{1+1.1/x^2}}{x} + 0.44.$$  

(12)

where $x=T/\Delta E$ is the scaled kinetic energy. Since the ratio for $\text{He}$ does not differ much from the calculated ratio for $\text{H}$, this comparison convinces us to use the $r(x)$ in Eq. (12) to describe the ratio for $D_2^+$ as well. The $r(x)$ indicates that $m=0$ is the dominant magnetic component in the present interested energy regime.

To relate the $2p_0$ or $2p_1$ partial cross sections to the excitation cross sections of $\sigma_u$ and $\pi_u$ electronic states of $D_2^+$, we need to know the alignment angle of the molecule. If the molecule is aligned along the laser field polarization direction (which is also the direction of the electron beam), the $2p_0$ cross section is the excitation to $\sigma_u$ state and the $2p_1$ ($2p_{-1}$) cross section is for the excitation to the $\pi_u$ state. If the molecule is aligned perpendicular to the laser polarization direction, then the role is reversed, i.e., $2p_1$ (or $2p_{-1}$) corresponds to the cross section of the $\sigma_u$ excitation, and $2p_0$ cross section to the $\pi_u$ excitation. For any arbitrary alignment angle $\theta$ of $D_2^+$, we assume the total excitation cross sections to $\sigma_u$ and $\pi_u$ are given by

$$\sigma(\sigma_u) = \sigma_T(r_0 \cos^2 \theta + r_1 \sin^2 \theta)$$  

(13)

$$\sigma(\pi_u) = \sigma_T(r_0 \sin^2 \theta + r_1 \cos^2 \theta).$$  

(14)

$$\sigma_T = \sigma_0 + 2\sigma_1$$  

(15)

$$r_0 = \frac{\sigma_0}{\sigma_T} = \frac{r(x)}{r(x) + 2}$$  

(16)

$$r_1 = \frac{2\sigma_1}{\sigma_T} = \frac{2}{r(x) + 2}. $$  

(17)

The semi-empirically fitted electron impact ionization or excitation cross section formulae discussed so far are for a free electron colliding with an atomic or molecular ion. For the rescattering process, the two electrons in $D_2$ initially are not in the singlet state ($S=0$). Thus in principle, one should just use singlet excitation or ionization cross sections, instead of the spin-averaged cross sections. We obtain the singlet cross sections from the total cross section following the empirical formula derived in Yudin and Ivanov 24 [their Eqs. (8) and (9)].

These empirical formulae allow us to calculate electron impact excitation cross sections from $\sigma_g$ to $\sigma_u$ and to $\pi_u$ states at each internuclear separation and at each alignment of the $D_2^+$ ion. In Fig. 6 we compare the electron impact excitation cross sections at the equilibrium distance to $\sigma_u$ and $\pi_u$ states, for $D_2^+$ ions lying parallel and perpendicular to the incident electron direction which is also the direction of the laser polarization, respectively. When $D_2^+$ is aligned parallel to the laser polarization, impact excitation to $\sigma_u$ is the dominant channel. The $\pi_u$
cross sections are smaller due to two factors: (1) the \( \pi_u \) state has higher excitation energy, see Fig. 2; (2) the \( 2p_0 \) state has larger cross sections than \( 2p_1 \) for the electron energies considered, see Fig. 3. The situation is different when \( D_2^+ \) ions are aligned perpendicular to the laser polarization direction. Fig. 3(b) indicates that excitation to the \( \pi_u \) state is actually larger than that to the \( \sigma_u \) state, at least in the 20-80 eV energy region. Note that in the experiments ofNiikura et al., the \( \text{H}_2^+ \) or \( \text{D}_2^+ \) were chosen to be perpendicular to the laser polarization direction. They assumed that electron impact excitation populates only the \( \sigma_u \) state, in disagreement with our analysis.

The semi-empirical formula presented above allows us to calculate electron impact excitation cross sections to \( \sigma_u \) and \( \pi_u \) states averaged over the initially randomly distributed \( D_2^+ \) ions. We obtained the ratio of the cross section of \( \sigma_u \) with respect to \( \pi_u \), and compared the result with the ratio obtained by Peek, where the impact excitation cross sections for different internuclear separations were calculated using the Born approximation. The agreement is quite good, with the average cross section for \( \sigma_u \) about a factor of two larger than for \( \pi_u \). The absolute cross sections from Peek are larger since Born approximation was used.

We also consider the small contribution from excitation to the \( 2s\sigma_g \) electronic state of \( D_2^+ \). The empirical formula is chosen to be

\[
\sigma_e(T, \Delta E) = \frac{1}{\Delta E^2} f(T/\Delta E) \tag{18}
\]

where the parameters \( A = 0.17 \), \( B = 1.53 \) are obtained by fitting the formula to the 1s \( \rightarrow 2s \) excitation cross sections of H. This cross section is assumed to be independent of the alignment of the molecular ion.

### E. Impact excitation probability

With all the elementary cross sections available, we can now calculate the probability distribution of exciting \( D_2^+ \) at a given internuclear separation \( R \) from the ground \( g \) state to a specific excited electronic state or to ionization states by the returning electron where the returning electron originates from the ionization of \( D_2 \) molecule by the laser over a half optical cycle. The probability distribution is given by

\[
dP_m = \frac{\int \int P_m(b, T) \chi^2(R, t_r) g(v) W(F \cos \phi) d\phi dv}{\int \int g(v) W(F \cos \phi) d\phi} \tag{19}
\]

The subscript \( m \) stands for the excited states \( (\sigma_u, \pi_u, \sigma_g) \) or ionization. \( P_m(b, T) \) is the impact excitation or ionization probability from Eq. 3. In this expression, \( W \) is the MO-ADK rate for ionizing \( D_2 \) at the static field \( F \cos \phi \), where \( F \) is the peak field strength of the laser. For each \( \phi \), the tunnelled electron leaves the molecule with an initial velocity \( v \), with a distribution governed by Eq. 4, i.e., effects due to both the longitudinal and transverse velocity distributions are included. For each initial velocity and initial position of the tunnelled electron, the return time \( t_r \) at the distance of closest approach, the corresponding laser-free impact parameter \( b \) and kinetic energy \( T \) are calculated, and the excitation probability is also calculated. At each return time \( t_r \), the distribution of the vibrational wave packet, \( \chi^2(R, t_r) \), is used to calculate the probability of finding \( D_2^+ \) at internuclear separation \( R \). In this expression the MO-ADK rates and the impact excitation probabilities to \( \sigma_u \) and \( \pi_u \) states depend on the alignment of molecules. The other quantities are isotropic. For \( D_2 \) initially aligned perpendicular to the direction of the linear polarization of the laser, the impact excitation probabilities at different \( R \)’s over half an optical cycle are shown in Fig. 7, where the peak laser intensity is 1.5 \( I_0 \). Note that excitation probability to \( \pi_u \) is the largest, but to \( \sigma_u \) is also significant. On the other hand, excitation to \( 2s\sigma_g \) excited state and direct ionization by the rescattering electron are not important.

It is interesting to point out that the probability of excitation in Fig. 7 shows distinct sharp peaks as a function of \( R \). To disentangle the source of these peaks, in Fig. 8 we examine the contributions to the \( \pi_u \) excitation probability according to whether the return time \( t_r \) falls within
one, two, three or four optical cycles after the tunneling electron is born. The excitation probabilities are larger for returns within one or two optical cycles. Within the first two optical cycles, the nuclear wave packets remain at small $R$ with small spreading and the returning electron has more kinetic energy (see Fig. 3). For the higher returns the nuclear wave packet moves to larger $R$ and spreads further and the smaller energies for the returning electron render the excitation probabilities smaller.

We comment once again that with the inclusion of Coulomb attraction on the motion of the rescattering electron, the maximum returning electron energy is not given by $3.17U = 29$ eV for the present peak intensity, but rather by $35$ eV, as seen from Fig. 4. This has the effect of enhancing the excitation to the $\pi_u$ state as well.

For peak laser intensity of 1.5 $I_0$ the results in Fig. 7 show that direct impact ionization of $D^+_2$ by the rescattering electron is very small. The rescattering mostly populates $D^+_2$ in the excited $\pi_u$ and $\sigma_u$ states. The dissociation of $D^+_2$ from an excited electronic state would release a total kinetic energy given by $U(R) - U(\infty)$, shared equally by $D$ and $D^+$, respectively. According to Fig. 7 excitation by the rescattering process peaks at characteristic internuclear separations related to characteristic rescattering time $t_r$, thus measurement of the $D^+$ fragment kinetic energies probes directly the recollision times. This forms the basis of molecular clocks in the experiments of Niikura et al. \cite{36, 34}. However, as shown in Tong et al. \cite{30} and in Alnaser et al. \cite{26}, the excited $D^+_2$ ions are still in the laser field and they can be further ionized by the lasers. Thus we need to calculate the kinetic energy spectra of $D^+$ resulting from Coulomb explosion after these excited $D^+_2$ ions are ionized by the laser.

**FIG. 7:** Electron impact excitation and ionization probabilities of $D^+_2$ by the rescattering electron following tunneling ionization of $D_2$ by a short pulse laser with peak intensity of 1.5 $I_0$ ($I_0 = 10^{14}$ W/cm$^2$) and pulse length of 40 fs.

**FIG. 8:** Electron impact excitation probabilities by the rescattering electron to the $\pi_u$ state in the first four optical cycles after $D_2$ molecules are ionized by a short pulse laser of peak intensity of 1.5 $I_0$ ($I_0 = 10^{14}$ W/cm$^2$) and pulse length of 40 fs.

F. Field ionization of excited $D^+_2$ ion

In this subsection we consider the ionization of $D^+_2$ from the excited electronic states. We emphasize that we will consider peak laser intensity within 0.5-5 $I_0$ only where rescattering is important. In this intensity region, $D^+_2$ is readily ionized if it is in the $\pi_u$ excited state since its saturation intensity is only about 0.1 $I_0$ because of small ionization energy. Thus we need only to calculate the ionization rate of $D^+_2$ from the $\sigma_u$ state. If the initial excitation to $\sigma_u$ occurs at $R$, the total accumulated probability for ionizing an electron by the laser field from the $\sigma_u$ state is

$$P_i(R, \infty) = 1 - e^{-\int W(R') dt}$$

$$= 1 - e^{-\int_{R}^{\infty} W(R')/v(R') dR'},$$

(21)

with

$$\frac{1}{2} \mu v^2(R') = U(R) - U(R').$$

(22)

where $W(R')$ is the MO-ADK tunneling ionization rate described in subsection A, $\mu$ is the reduced mass of the two nuclei, and $U(R)$ is the total potential energy of the $\sigma_u$ state. The $\sigma_u$ state created at $R$, followed by laser field ionization at $R'$ will release a kinetic energy

$$E_i(R') = U(R) - U(R') + 1/R'.$$

Here we are more interested in the differential ionization probability which is given by

$$\frac{dP_i(R, R')}{|dR'|} = \frac{W(R')}{v(R')} e^{-\int_{R}^{R'} W(R'')/v(R'') dR''},$$

(23)

or in terms of differential probability per unit of kinetic energy

$$\frac{dP_i(R, R')}{|dE|} = \frac{dP_i(R, R')}{|dR'|} \frac{dR'}{|dU|}$$

(24)

$$= \frac{1}{|\frac{dU}{dR'}|}.$$
In all other excited electronic states the D\(^+\)+ ions are immediately ionized by the laser in one optical cycle. The total dissociation spectra are obtained by adding up contributions from initial ionization at all values of \(R\), i.e.,

\[
\frac{dP_{\text{ion}}}{dE} = \int \frac{dP_m}{dR} \frac{dP_i(R, R')}{dE} dR
\]

This integration is important primarily only for ionization from the excited \(\sigma_u\) state. For other excited electronic states, due to the high ionization rate, ionization is complete within one cycle or less and we can set \(R = R'\), and the differential ionization spectra for these excited electronic states are given by

\[
\frac{dP_{\text{ion}}}{dE} = \frac{dP_m}{dR} \frac{dR}{dU}.
\]

The total ionization spectra are obtained by adding up contributions from all the excited electronic states, and from the initial ionization by the rescattering electron (very negligible).

For the dissociation process, the energy spectra are obtained from

\[
\frac{dP_{\text{dis}}}{dE} = (1 - P_i(R)) \frac{dP_m}{dR} \frac{dR}{dU}.
\]

The total dissociation spectra are obtained by adding up contributions from all the excited electronic states. In reality, the dissociation comes from the \(\sigma_u\) excited state only. In all other excited electronic states the D\(^+\) ions are immediately ionized by the laser in one optical cycle.

high energy peak near 16 eV from the theory is too high, while the theoretical spectra between 5 and 10 eV are somewhat too low. However it appears that the discrepancy can be reconciled if one takes into account of the volume effect in that the experimental spectra have to be integrated over a volume where the intensities are less than the peak value. The energy resolution and the finite acceptance angles can all contribute to the smoother experimental spectra. One of course should also take this "better agreement" with caution in view that the peak intensity of the laser is often not known precisely.

One of the major goals of the simulation is to unravel the origin of the structure in the kinetic energy spectra which in turn would provide insight of the working of the molecular clock. For this purpose, we show in Fig. 11 the calculated kinetic energy spectra, but separate the contributions from dissociation and ionization, and from rescattering occurred after one or two optical cycles, or equivalently, from the first (t₁) or the third returns (t₃), at two laser intensities, 1.5 and 0.8 I₀. At the higher intensity, in this figure we notice: (1) ionization is much stronger than dissociation; (2) the peak from the third return (2nd cycle) is higher than from the first return; (3) The width of the peak from the first return is broader than the peak from the third return. The broadening is a consequence of the factor dR/dU in Eqs. (26) and (28) which is approximately given by R². Another interesting observation is that the peak position of the dissociation spectra from the first return almost coincides with the peak position in the ionization spectra from the third return. This shift is due to the binding energy of the excited electronic states.

In Niikura et al.'s experiment [4] the peak at 12 eV was attributed to originate from the dissociation of D₂⁺ via the σᵤ curve at the first return. In other words, this peak reads the clock at t₁. According to our simulation, the peak comes from ionization following rescattering at the third return, and this peak should read the clock at t₃.

Contributions to the D⁺ signal from dissociation do become more important at lower laser intensity, as shown in Fig. 11(b). Even at this intensity, the peak at 12 eV still comes mostly from the ionization following rescattering at t₃ instead of dissociation following rescattering at t₁. Furthermore the third return peak is higher than the first return peak for either dissociation or ionization. We remark that the spectra in Fig. 11 were calculated including contributions up to four or five optical cycles after the initial tunneling ionization and convergence of the calculation was checked.

**B. D⁺ coincident kinetic energy spectra**

The D⁺ ion kinetic energy distributions in laser-D₂ interactions have been determined in coincidence measurements where the two D⁺ ions were detected simultaneously by Staudte et al. [2] and more recently by Alnaser et al. [27]. In the latter experiment, the branching ratios of ionization with respect to dissociation had been measured as well, for peak laser intensities of 1-5 I₀. Their data for peak intensity of 2.8 I₀ are shown in Figure 12. The experiment used a 35 fs pulse with mean wavelength of 800 nm. The D⁺ spectra are from Coulomb explosion of ions at 60-80° with respect to the direction of the linear polarization of the laser field. In the figure we show the result of our theoretical simulation for laser intensity of 2.0 I₀. We found best overall agreement with the experimental data at this intensity without considering volume effect and the fact that the theoretical calculation was carried out for molecules aligned perpendicular to the laser polarization while the experiments measured ions coming out of 60-80° with respect to the laser polarization. The simulated spectra near the kinetic energy peak region of 7-12 eV agree quite well with the data, but the peak near 17 eV is more pronounced in the simulation.

A direct comparison of simulated kinetic energy spectra with experimental data is complicated in general not only by the volume effect, the angular resolution of the D⁺ product, but also the difficulty of knowing the peak laser intensity precisely. In Fig. 13 we show the yield

![Image](image_url)
FIG. 12: Comparison of D$^+$ ion spectra resulting from the double ionization of D$_2$ molecules in a laser field. The experiment data are from Ref. 26 for peak laser intensity of 2.8 $I_0$ and the theoretical simulation is for laser peak intensity of 2$I_0$, where $I_0=10^{14}$ W/cm$^2$ and the pulse length is 35 fs.

FIG. 13: Simulated D$^+$ ion yield from the double ionization of D$_2$ by the rescattering process at several peak laser intensities in units of $I_0=10^{14}$ W/cm$^2$. The pulse length is 35 fs.

for making two D$^+$ ions vs the total kinetic energy for peak laser intensity from 1.0-3.0 $I_0$. The calculations were done for 35 fs pulse and mean wavelength of 800 nm and with molecules aligned perpendicular to the laser polarization direction. Clearly the yield increases rapidly with laser intensity. We further note that the peak positions in the spectra do change with laser intensity. In particular, the main peak shifts to lower kinetic energy at higher laser intensity. To understand the reason of this shift, in Fig. 14 we separate the kinetic energy peaks into contributions from the $\sigma_u$ and from the $\pi_u$ curves, and for rescattering occurring after one, two and three optical cycles following tunneling ionization. Recall that we consider D$^+$ from ionization only here. At 2.0 $I_0$, we note the larger contribution comes mostly from ionization of D$_2^+$ in the $\pi_u$ state, although contribution from $\sigma_u$ is not negligible. From Fig. 14(b) one can clearly identify the two peaks approximately at 10 and 12 eV in Fig. 12 can be attributed to ionization from $\sigma_u$ and $\pi_u$, respectively, for rescattering collision from the third return. At 3.0 $I_0$ (Fig. 14(a) ), due to the larger contribution from the $\sigma_u$ excited state, the peak positions in the kinetic energy spectra are shifted to lower values. Thus the sum kinetic energy spectra at the two higher intensities look different from those at lower intensities, as seen in Fig. 13. Fig. 14(a) also shows that contribution from the third cycle becomes relatively more important at higher intensity. At higher intensity, the rescattered electron has larger kinetic energy. Thus it takes more time for the Coulomb attraction to bring the electron to come near the ion for the rescattering to occur.

Figure 14 also illustrates how the working condition for using rescattering model to measure the precise time in a molecular clock can be limited. The kinetic energy spectra from each excited electronic state of D$_2^+$ has relatively well specified and distinct peak positions from the first, 3rd and 5th returns. Such peak positions immediately give information about the molecular clock since each peak position does not depend on the laser inten-
sity. However, when ionization from $\sigma_u$ channel also contributes then the combined sum would shift the peak positions as the laser intensity is changed, as shown in Fig. 13. Thus to read the molecular clock accurately, one has to choose laser intensity where only one of the excited $D_2^+$ electronic states contributes mostly to the ionization signal. Failure to do so would compromise the accuracy of the clock. Since the relative contributions of the ionization signals from $\sigma_u$ and $\pi_u$ are expected to change with laser intensity and with the alignment of the molecules, this also helps explain why the valleys in the experimental spectra are usually less sharply peaked than the ones simulated from the theory at a given peak laser intensity.

C. Laser- $H_2$ interactions and wavelength dependence

Clearly the present method can be used to predict the kinetic energy spectra if $H_2$ is used as the target. The only difference in $H_2$ is that it has smaller reduced mass such that the wave packet propagates faster, and thus kinetic energy spectra will be shifted to lower energies. If the wavelength of the laser is increased, the period is longer and thus the kinetic energy spectra also will shift to lower energies. We have applied the present theoretical model to study the comparison of kinetic energy spectra taken for $H_2$ and $D_2$ simultaneously \[20\], and also the variation of the kinetic energy spectra when wavelength was varied as in the experiment of Niikura et al. \[1\], see Tong et al. \[36\].

IV. SUMMARY AND CONCLUSION

In this paper we have provided a comprehensive study of the elementary processes of the rescattering mechanism leading to the fragmentation of $D_2^+$ following the initial tunneling ionization of a $D_2$ molecule in a short intense laser pulse. Ionization rates of $D_2^+$ from the excited electronic states and impact excitation and ionization cross sections by the returning electron have been obtained based on the MO-ADK theory and from semi-empirical formulation, respectively. Following the initial idea of Corkum and coworkers, we showed that the kinetic energy spectra of $D^+$ in the higher energy region (5 to 10 eV per $D^+$ ion) can be used as a molecular clock which can be read with subfemtosecond accuracy. Through our detailed simulation, we concluded that the dominant peak in the $D^+$ kinetic energy spectrum is due to the further ionization of the excited $D_2^+$ following impact excitation by the returning electron, and this excitation occurs not at the first return but mostly at the third return. We have compared our simulation results with the recent experiments of Niikura et al. and of Alnaser et al. with general good agreement. Further experimental studies in terms of dependence on laser wavelength, pulse duration and alignment angles may provide more critical test on the present theoretical model. From the theoretical viewpoint, despite of the semi-empirical nature of the present modeling, we do not expect any meaningful pure \textit{ab initio} quantum calculations viable in the foreseeable future. The present model has the further advantage that the mechanism for producing each individual peaks in the kinetic energy spectra can be identified and the effect of laser parameters can be readily tested. On the other hand, the semi-empirical nature of the modeling can claim its reliability only after it has been exposed to more stringent tests from the experiment.
