A simple and sensitive method to determinate glucose content was developed based on single plasmonic nanoparticles by conventional dark-field microscopy (DFM). An enzyme-responsive plasmonic Ag/Au bilayer of rods was designed and prepared. Their localized surface plasmon resonance (LSPR) could be tailored by the enzyme reaction of glucose oxidase (GOx) by finely tuning the morphology and plasmonic optical response of the hybrid nanostructure. It was found that the plasmon resonance scattering (PRS) spectra peak (λmax) shifted to longer wavelengths under enzyme reactions, and the degree of the shift were proportional to the content of glucose. This approach is convenient to study the local concentration of glucose in real time.

Introduction

Noble metallic nanoparticles have attracted significant attention for their unique tunable size, shape and composition as well as their interesting catalytic, electronic, and plasmonic optical properties.1–4 The optical properties of metal nanoparticles are determined by localized surface plasmon resonance (LSPR), which is influenced by many aspects, such as the size, shape, composition and the surrounding medium.5–8 Among nanoparticles with various shapes, an anisotropic Au nanorod (NR) has attracted considerable attention in the past few years because of their high sensitivity to the local refractive indices of the surrounding medium.9–11

Recently, bio-inspired enzyme-responsive plasmonic metal nanoparticles have become attractive since hybrid nanoparticles (NPs) have potential applications in biosensing and bioelectronics when their LSPR bands shift in response to bioreognition events or enzyme-catalyzed reactions.12–18 Most of these studies on biosensing applications have been done in solution using the UV-Vis or the surface plasmon resonance (SPR) spectrum, which washes out the analysis and tracking of individual nanoparticles. Besides, these nanomaterials are easy to aggregate in solution and hard to prepare. Therefore, new methods need to be developed to detect biomolecules. Dark-field microscopy (DFM), because of its real-time optical sensing and high sensitivity, has been used to directly observe chemical reactions by studying single plasmonic NPs.19–21

Herein, we report on an interesting hybrid enzyme-responsive Au/Ag bimetallic nanorod (NR) system for in situ sensitive optical glucose sensing and real-time monitoring the activity of enzymes. The enzyme reaction was monitored at the single-nanoparticle level using a real-time color imaging and plasmon resonance scattering (PRS) spectra shift, which could be observed by a charge-coupled device (CCD) camera and a spectrometer, as depicted in Scheme 1.

The principle of this experiment is that the surface-modified enzyme can oxidize the glucose to generate hydrogen peroxide in the presence of oxygen, which can dissolve silver to regulate the thickness of the silver coating around gold nanorods.15,22–24 Using above-mentioned principle we can tune the LSPR of Au/Ag NRs by the enzyme reaction of glucose oxidase (GOx) through fine tuning the morphology and plasmonic optical response of the hybrid nanostructure. The reactions can be described as follows:

\[
\text{GOx-glucose} + \text{O}_2 \rightarrow \text{d-gluconic acid} + \text{H}_2\text{O}_2, \quad (1)
\]

\[
2\text{Ag} + \text{H}_2\text{O}_2 \rightarrow 2\text{Ag}^+ + 2\text{OH}^- \quad (2)
\]

Experimental

Reagents and chemicals
All reagents were of analytical grade and used without further purification. All solutions were prepared with Milli-Q water from a Millipore system and quantified using UV-Vis absorption spectroscopy. Milli-Q water with a resistivity of 18.2 MΩ was used in all preparations.

Apparatus
The morphologies of the samples were characterized by scanning electron microscopy (SEM; EDAX-4800) and transmission electron microscopy (TEM; Japan JEOL-2010). Light-scattering spectra were recorded using a Cary Eclipse fluorescence spectrophotometer (Agilent Technologies, USA). Dark-field images were acquired on a Nikon inverted microscope Eclipse Ti-U equipped with a color charge coupled device (CCD; S45, Canon, Japan). The scattering spectra of single nanoparticles were recorded using an SP2560 spectograph equipped with a 512B_excelon electron multiplying charge coupled device (Princeton Instruments, USA) and mounted on a Nikon microscope. Glass slides were cleaned under a PSD-UV4 ozone system (Novascan Technologies) before use. All tests were carried out at room temperature.

In order to measure the PRS spectrum, NRs were first immobilized on a piece of glass slip by physical adsorption. Before using, the slide was washed with ethanol and distilled water thoroughly, and was then irradiated under an Ultra-Violet/Ozone cleaner for 1 h. Then, a piece of polydimethylsiloxane (PDMS) with a 6-mm hole was covered on the glass. The hole on the PDMS then was used as a container for an NRs solution for later glucose measurements. Next, a drop of diluted Au/Ag NRs solution (~0.01 nM) was added in the PDMS hole and allowed to contact with the glass surface for 30 min to obtain a reasonable surface density of single nanoparticles. The glass was then washed with pure water three times in order to remove free NRs in the solution. During the following measurement, a drop of 10 mM PBS (200 μL) always covered the glass. A dark-field imaging mode of the microscope was first used to obtain images of single NRs. The PRS spectra of the single NR were recorded by turning the light pathway to a spectrometer connected on the microscope. An electron multiplying charge-coupled device (EMCCD) was used to record the spectra.

Results and Discussion
The Au/Ag bimetallic NRs used as sensing platforms were first synthesized as reported.25 Figure 1 shows SEM images of the precursor Au NRs (Fig. 1a), TEM images of hybrid Au/Ag NRs (Fig. 1b) and the UV absorption of Au/Ag solution and Au/Ag immobilized on the glass slide (Fig. 2e). All of the above characterizations indicate that the Au/Ag NRs had a uniform size. The average diameter and length of the Au/Ag NRs were 12 ± 1 and 51 ± 3 nm, with a shell thickness of 2 – 3 nm. The Au/Ag-GOx NR complex was then formed by electrostatic adsorption of the negatively charged GOx protein (PI = 4.2) onto the positively charged and CTAB-coated NRs surface at pH 7.4. During the process, an excess amount of GOx was used to reach the monolayer saturation adsorption on the NRs surface; then, any excess GOx was removed before the addition of glucose.

Scattering images and spectra of GOx-modified Au/Ag NRs were obtained using DFM coupled with a spectrograph. As shown in Fig. 2f, a small spectral redshift of about 2 nm occurred after GOx was electrostatically attached onto the Au/Ag NR surfaces. The scattering peaks of the complex Au/Ag-GOx NRs for longitudinal plasmon resonance were mostly around 620 nm (Fig. 2b) with a red color (Fig. 2a). However, upon the addition of glucose, a redshift of the scattering spectrum took place, and changes in the imaging color and brightness in the dark field were also observed (Figs. 2c – 2d). The statistics of 25 spectra of colored NRs shows that most of their peak positions are around 620 nm, and that the stability and reliability of each NR are acceptable. The control experiment shows that the maximum peak of every single NR, itself, will not shift for hours. The above data provided a basis for designing the nanosensor using a single Au/Ag NR. Figure 2f shows typical PRS spectral changes of the Au/Ag-GOx NRs, before and after incubation with glucose for 60 min. From the scattering spectra, it is clear that the max of the scattering spectrum of the Au/Ag-GOx NRs exhibits a peak redshift of about 12 nm. Meanwhile, the applicability of this sensing system was investigated. The changes in the scattering shift of NRs were determined after incubation with various concentrations of glucose (10⁻⁵ – 10⁻⁴ M). Dots with similar color and brightness were chosen in the CCD so as to discuss the relationship between the λmax shifts and the glucose concentrations, because the NRs’ sizes and their delicate surface environments were not the same. As shown in Fig. 3a, the higher was the glucose concentration, the bigger did the shift of the max of the PRS spectrum become. In addition, the shift was found to be linear with the glucose concentration from 0.5 × 10⁻⁵ to 10⁻⁴ M (Fig. 3d). The detection limit (LOD) was 0.5 μM, under the concentration in which the scattering spectrum shifts by around 4 nm, which is lower than those obtained using reported fluorescence detection methods.26–29 However when the glucose concentration was above 0.5 mM, the shift of spectrum peaks reached a saturation value of 13 nm, since the Ag outer Au Rods all became dissolved. The control experiment showed that no detectable spectra shift of the Au/Ag NRs (GOx-free) occurred after incubation with 3 × 10⁻⁴ M of glucose for 60 min. A quantitative analysis of the scattering λmax statistical distribution of the nanoparticles before and after the reaction was also performed (Figs. 2b and 2d). Because of the shell change outside the Au NR, a shift of the spectrum was recorded before and after etching. The successful PRS spectra λmax response of single Au/Ag NRs exhibited a distinct peak-shift behavior toward longer wavelengths, the average shift was about 15 nm.

In order to better know the sensing progress, we investigated the time-dependent evolution of the scattering spectra of the as-prepared Au/Ag-GOx NRs incubated with 3 × 10⁻⁴ M glucose solutions. The data in Fig. 3d indicate that the sensing progress,
was separated into two stages. First, the PRS spectra peak of the nanorods gradually red-shifted upon the addition of glucose; it then stopped increasing, and became steady to a saturation value after about 1 h. We also found that the higher was the glucose concentration, the faster did the reaction rate become.

The morphology of the particles was characterized by TEM. After being treated by \(3 \times 10^{-4} \text{M}\) glucose for 20 and 60 min, a noticeable collapse appeared on the side of the nanorods, as shown in Fig. 3b. The TEM images indicate that some ultrafine particles scattered around the nanorods, which was caused by forming and losing of the silver oxide on the NRs’ shell after the complex NRs were incubated with glucose. Once the solution encountered disturbances, the outer shell would collapse and the outlines of the NRs will changed (Fig. 3b inset), indicating that \(\text{H}_2\text{O}_2\) could act as a mild etchant to dissolve Ag from bimetallic nanostructures.

Control experiments were carried out in order to investigate the specificity for glucose sensing of the system. As shown in Fig. 4, there was almost no scattering peak shift of Au/Ag-GOx NRs for the fructose, lactose, and sucrose at the same concentrations as glucose.

**Conclusions**

In summary, the complex Au/Ag-GOx bimetallic NRs was synthesized, and showed good enzymatic activity. It can thus be exploited as a new method for *in situ* real-time sensitive optical glucose sensing. By taking advantage of the etching effect of \(\text{H}_2\text{O}_2\) generated from the enzymatic oxidation of glucose, glucose can determine the rate of dissolution of silver so as to adjust the shell thickness of Au NRs, which can be used to tailor the plasmonic response of the nanoparticle sensors. The analytical method based on the biological sensing of single plasmonic nanoparticles is more simple and sensitive than colloidal plasmonic Au/Ag-GOx NR nanocomplexes, which tend to aggregate and require more centrifugation steps. The enzyme-responsive nanocomplex system that we developed here is promising, and could be used as a new analytical platform for the single-particle tracking of \(\text{H}_2\text{O}_2\) or glucose in live cells.
