We study the jamming phase diagram of sheared granular material using a novel Couette shear set-up with multi-ring bottom. The set-up uses small basal friction forces to apply a volume-conserving linear shear with no shear band to a granular system composed of frictional photoelastic discs. The set-up can generate arbitrarily large shear strain due to its circular geometry, and the shear direction can be reversed, allowing us to measure a feature that distinguishes shear-jammed from fragile states. We report systematic measurements of the stress, strain and contact network structure at phase boundaries that have been difficult to access by traditional experimental techniques, including the yield stress curve and the jamming curve close to \( \phi_{SJ} \approx 0.75 \), the smallest packing fraction supporting a shear-jammed state. We observe fragile states created under large shear strain over a range of \( \phi < \phi_{SJ} \). We also find a transition in the character of the quasi-static steady flow centered around \( \phi_{SJ} \) on the yield curve as a function of packing fraction. Near \( \phi_{SJ} \), the average contact number, fabric anisotropy, and non-rattler fraction all show a change of slope. Above \( \phi_F \approx 0.7 \) the steady flow shows measurable deviations from the basal linear shear profile, and above \( \phi_c \approx 0.78 \) the flow is localized in a shear band.

Keywords: Granular matter, Shear jamming, Strain amplitude, Couette multi-ring bottom geometry, Photoelectricity

When a granular material prepared in a stress free state is sheared, it can make a transition into a mechanically stable state through a process known as shear jamming [1]. Shear jamming occurs in many different systems, including glasses [2], suspensions [3-8] and dry granular matter with [1, 9-13] or without [14-17] friction. In 2011, Bi et al. [1] provided a jamming phase diagram (Fig. 1a) that extended the Liu-Nagel framework [18] by including a region of shear-jammed (SJ) states for frictional granular materials at finite shear stress with packing fractions \( \phi \) between a critical value \( \phi_{SJ} \) and \( \phi_0^{SJ} \), the isotropic jamming packing fraction for frictionless particles. Starting from a stress free state, applying shear strain \( \gamma \) can lead to two different types of jammed states: fragile (F) states that are only stable for compatible loads, and SJ states that are stable to reverse shear [1, 19]. A minimum shear strain \( \gamma_{SJ}(\phi) \) is needed to create a SJ state for fixed \( \phi \). In the past decade, many efforts have focused on explaining the origin of rigidity in sheared granular matter with \( \phi \) close to the high packing fraction portion of the jamming curve (the yellow curve in Fig. 1a) [1, 12, 15, 20-23]. However, less attention has been paid to other parts of the phase diagram, in particular to the yield stress curve, which is important for the rheology of dense granular flow, or to the jamming curve close to the critical packing fraction \( \phi_{SJ} \), where the relation between the shear strain \( \gamma \) and jamming has not been experimentally determined.

Experimental measurements of the phase boundaries in the jamming phase diagram are challenging because it is hard to create SJ states without the formation of a shear band and the associated heterogeneities in the packing fraction \( \phi \) and strain field [1, 10, 24, 25]. In 2013, Ren et al. [10] developed a multi-slat, simple shear setup that avoids shear banding, which revealed a distinction between F and SJ states [24, 26]. However, their multi-slat setup had a strain limit (\( \sim 60\% \)) [10], and thus could not access the yield stress curve or the SJ states near \( \phi_{SJ} \), where \( \gamma_{SJ} \) keeps growing as \( \phi \to \phi_{SJ}^{F} \) [1, 11, 15, 16].

In this letter we solve this challenge using a multi-ring Couette shear set-up, which applies a linear shear strain field using basal friction forces to drive the system until it becomes shear-jammed. This form of driving may be thought of as a physical implementation of the algorithm used in certain athermal, quasistatic (AQS) simulations [20, 29]. With our apparatus, we can also keep shearing the jammed system using boundary racks to measure the yield stress curve. By shearing a layer of photoelastic disks, we for the first time experimentally map out the phase boundaries in the jamming phase diagram close to \( \phi_{SJ} \), including the yield stress curve and the jamming curve. We find that fragile states exist below \( \phi_{SJ} \) that were not included in the traditional phase diagram [1]. Moreover, we find two transitions on the yield stress curve: (i) above \( \phi_F \approx 0.7 \), the steady states no longer deform linearly under shear, and (ii) above \( \phi_c \approx 0.78 \) their deformation field becomes localized. We relate those transitions to the contact network structures.

Experiments — The experiments are carried out with a novel multi-ring Couette shear set-up shown in Fig. 1b,
which quasi-statically and linearly shears a 2D granular medium composed of bidisperse photoelastic discs with friction coefficient 0.9 and diameters 1.59 cm and 1.27 cm (denoted as d). The ratio of the numbers of big and small particles is 1/3. Particles have reflective paint on their bases to enable reflective photoelasticimetry. The total number of particles is varied from 1447 to 2101, which corresponds to 0.56 < φ < 0.82. The Couette set-up consists of 21 independently controlled concentric rings. The 1.2 cm wide rings rotate collectively, providing weak frictional forces to the particles sitting on them. Although essential to perform the linear shear, the magnitude of basal friction is ~8 times smaller than the typical contact forces measured in the SJ states on the jamming curve (Fig. 1(a)). Particles are constrained radially by outer and inner toothed boundaries of radius \( r_{out} = 35.5 \text{ cm} \) and \( r_{in} = 8.7 \text{ cm} \). The outer boundary rotates with the rings and the inner boundary is fixed.

For each experiment, a stress-free random configuration is prepared. The quasi-static linear shear is then applied in a stepwise manner. For each step, the ring at radial position \( r \) rotates through an arc length \( d(r) = \gamma r \). The function \( d(r) \) sets the ‘basal profile’ and \( \gamma \) is called the ‘shear strain’ by analogy with traditional simple shear. We note that \( \gamma \) is not the physical shear strain, i.e., the off-diagonal element of the strain tensor. During a rotation step, in which \( \delta \gamma = 0.6\% \), the shear rate is \( \dot{\gamma} \sim 10^{-3} \text{s}^{-1} \). After each step, the rings stop for 10 s to let the system reach a static state. As plotted in Fig. 1(c), for a dilute system, the azimuthal particle displacements \( u_\phi \) per step follow \( d(r) \), and the radial displacements \( u_r \) fluctuate around zero. No shear band is observed. We apply large forward strains to measure the yield stress curve, and the strain direction is then reversed to distinguish fragile and shear-jammed states.

The system is sequentially lit from the top by circular polarized green light, and from the side by ultra-violet (UV) light. Between two consecutive shear steps, after reaching a static state, the system is imaged (Canon EOS 70D, 5472 \times 3648 \text{ px}^2) through a circular polarizer with UV and polarized lights. UV images (Fig. 1(e)) give particle positions. The polarized images (Fig. 1(d)) give stress and contact information. We measure the pressure \( P \), defined as the trace of the force moment tensor, using the averaged squared intensity gradient of the polarized image. A sheared system must develop a non-zero \( P \) to resist finite shear \( \tau \). We also measure the non-rattler contact number \( Z_{nr} \), defined as the mean contact number among stressed grains, the non-rattler fraction \( f_{nr} \), defined as the number fraction of stressed grains, and the fabric anisotropy \( \rho \), defined as the ratio between the difference and the sum of the eigenvalues of the fabric tensor.

(See Ref. [1] for a detailed description of the contact detection algorithm.)

**FIG. 1.** (color online) (a) The jamming phase diagram in the shear stress \( \tau \) and packing fraction \( \phi \) plane adapted from [31]. Only \( \phi < \phi^*_J \) part of the diagram is shown. The yield stress curve and the jamming curve are highlighted in blue and yellow, respectively. (b) Schematic of the multi-ring Couette set-up. 21 horizontal concentric rings rotate step-wisely to quasi-statically shear bidisperse photoelastic discs. For each shear step, ring at position \( r \) rotates by an arc length \( d(r) \). The nominal shear strain is defined as \( \gamma = d(r)/r \). (c) Particle displacements in radial (\( u_r \)) and azimuthal (\( u_\phi \)) directions in a shear step for a dilute system (\( \phi = 0.57 \)). The dashed line is the linear basal profile \( d(r) \). After each shear step the system is imaged in UV light (e) and in polarized green light (d).

![FIG. 2](image2.png)

**FIG. 2.** (color online) (a-b) The pressure \( P \) and the non-rattler contact number \( Z_{nr} \) versus \( \gamma \) for different \( \phi \) during forward shear. The dashed black curve in (b) plots the exponential fit by Eq. (1) for \( Z_{nr}(\gamma) \) with \( \phi = 0.78 \). The blue dashed line shows the \( \gamma_{max} \) value for this run. (c) Strain needed to reach the steady regime, \( \gamma_a(\phi) \). The black line is an exponential fit \( \gamma_a \sim (\phi - \phi_0) \) for \( \phi > 0.72 \). (d) \( P \) versus \( \gamma \) for a typical reverse shear test (\( \phi = 0.781 \)) with forward shear strain \( \gamma_{max} \). (e) The minimum pressure, \( P_{min} \), during the reverse shear versus \( \gamma_{max} \) for \( \phi = 0.781 \). \( \gamma_{SJ} \) is the minimum \( \gamma_{max} \) for which \( P_{min} > P_{noise} = 0.3 \text{ N/m} \) [31].
Results – Figures 2(a) and (b) show pressure $P$ and non-rattler contact number $Z_{nr}$ versus shear strain $\gamma$, for typical runs with different $\phi$. For a given $\phi$, after a transient growth regime, both $Z_{nr}$ and $P$ fluctuate around constant values that define the yield stress curve. We refer the associated stress as the “steady states” stress. We find that $Z_{nr}$ can be fitted to:

$$Q = Q_{st} + c + e^{-\gamma/\gamma_c}$$  

(1)

where $Q$ can be $Z_{nr}$, $f_{nr}$ or $1 - \rho$, and $Q_{st}$, $c$ and $\gamma_c$ are fit parameters. An example fit for $Z_{nr}(\gamma)$ with $\phi = 0.76$ is plotted in Fig. 1b. We find that the steady regime has been reached at $\gamma_{st} \approx 3\gamma_c$ for all state variables, where $\gamma_c$ is obtained from the fits for $Z_{nr}$. Figure 2(c) shows $\gamma_{st}(\phi)$, where a linear fit $\gamma_{st} \propto (\phi - \phi_0)$ for $\phi > 0.72$ gives $\phi_0 = 0.84 \pm 0.02$, close to the frictionless isotropic jamming density [40]. The slope is $-1545 \pm 427$ (%).

We identify a system as shear-jammed (SJ) if under reverse shear the pressure never drops below the noise threshold $P_{noise} = 0.3$ N/m [31], which indicates that the system resists the reversed stress rather than simply allowing a reversion to a stress-free (unjammed) state. Figure 2(d) shows the evolution of $P$ during a shear cycle for a system with $\phi = 0.781$. Figure 2(e) plots the dependence of the minimum pressure $P_{min}$ during reverse shear on the maximum forward shear strain $\gamma_{max}$, from which we extract the minimum strain, $\gamma_{SJ}$, required to create a SJ state. We find no SJ state for $\phi = 0.74$ even when $\gamma_{max} \gg \gamma_{st}$ [31]. For $\phi = 0.75$, we find $\gamma_{SJ} \approx \gamma_{st}$. The minimum packing fraction that supports shear jamming must lie between these two values: $\phi_{SJ} = 0.745 \pm 0.005$. Figure 3(a) plots the relation between $\gamma_{SJ}$ and $\phi$, which can be fitted using a form suggested in Ref. [40],

$$\gamma_{SJ}(\phi) = \gamma_b \left( \frac{\phi - \phi_{SJ}}{\phi - \phi_{SJ}} \right)^\alpha$$  

(2)

where $\phi_{SJ} = 0.745$ is preset and the fit parameters are $\alpha = 0.68 \pm 0.11$, $\gamma_b = 64 \pm 6$ (%) and $\phi_0 = 0.820 \pm 0.005$.

In this work, fragile (F) states refer to states with non-zero pressure ($P > P_{noise}$) and have $P_{min} < P_{noise}$ at some point in the reverse shear process. As shown in Fig. 3(a), we find $\gamma_F$, the minimum strain required to create a fragile state, also follows Eq. 2. In this fit, we take $\phi_0 = 0.82$ from the previous fit, and we determine $\phi_F$, the minimum packing fraction for fragile states, from the fit, obtaining $\phi_F = 0.706 \pm 0.003$ along with $\gamma_b = 19 \pm 2$ (%) and $\alpha = 0.86 \pm 0.12$. We also note, however, that the divergence predicted by Eq. 2 near $\phi_{SJ}$ and $\phi_F$ is not clearly seen in our data. Below $\phi_F$, the steady state pressure falls to a plateau value near the noise level.

Figure 3(b) shows the experimentally constructed jamming phase diagram in the $(P, \phi)$ space. The yield stress curve is the $P_{st}(\phi)$ curve, showing the average steady state pressure for each $\phi$. $P_{st}$ increases monotonically from $\phi_F$ and appears to have an inflection point at $\phi_{SJ}$. However, for the steady states above $\phi \approx 0.78$, the pressure of some particles becomes so large that their photoelastic fringes cannot be resolved, likely leading to artificially low pressure measurements. $P_{st}(\phi)$ also separates SJ states and the dynamic unjammed states, which have non-zero shear rates. The jamming curve is also plotted as the $P(\phi, \gamma_{SJ})$ curve, which consists of the pressure value for each $\phi$ at the jamming strain $\gamma_{SJ}$. The gray region below $P_{noise}$ refers to the static unjammed states without measurable stress. Figure 3(e) extends (b) by including the inverted strain axis and plots all the static states measured during the forward shear process in the $(P, \phi, 1/\gamma)$ space, highlighting their dependence on the driving strain $\gamma$. A state is labeled SJ when the shear strain exceeds $\gamma_{SJ}$ determined using Eq. 2. All static SJ (green), F (red) and unjammed (gray) states lie approximately on a smooth surface in the 3D space.

To quantify the contact network structure on the yield stress curve, we measure $Z_{nr, st}$, $f_{nr, st}$ and $\rho_{st}$, which are obtained from fits to the form of Eq. 1. Figures 3(c) and (d) show a change in slope in all three state variables
at a packing fraction slightly above $\phi_{SJ}$. The red dashed line in Fig. 3(c) is the linear fit using data with $\phi > \phi_{SJ}$, which highlights the change in behavior at $\phi_{SJ}$. Figures 3(a) and (b) show two polarized images taken from the steady regime with packing fractions 0.72 and 0.78, showing typical force network in F and SJ states.

When the system is shear-jammed, the basal friction becomes unimportant, and the particle displacement field deviates from the basal profile. Based on the azimuthal displacement field per shear step averaged over the steady states, $u_{\theta,st}(r)$, we calculate the off-diagonal element of the strain tensor $\varepsilon_{r\theta,st}(r) = \partial_r u_{\theta,st}(r) - u_{\theta,st}(r)/(r + r_{in})$ [38], which gives the mean physical shear strain field for steady states (Fig. 3(c)). We also measure the width of the shear zone $w$, which is the radial position $r/w$ for which $\varepsilon_{r\theta,st}$ becomes smaller than the noise level 0.02%. Figure 3(d) shows $w(\phi)$ (in red), which jumps discontinuously near $\phi_c \approx 0.78$, below which $w = r_{out} - r_{in} \approx 20d$. Above $\phi_c$, $w \approx 7d$, denoted as $r_{bulk}$ in Fig. 3(c). The local packing fraction in this shear band is also smaller than the global value. The part of the system with $r > r_{bulk}$ just rotates as a solid with the moving outer boundary in the steady states for $\phi > \phi_c$. We also calculate $\varepsilon_{bulk}$, which is the averaged $\varepsilon_{r\theta,st}$ for $r > r_{bulk}$. Figure 3(d) shows $\varepsilon_{bulk}$ starts to drop at $\phi_F$ and becomes zero near $\phi_c$.

Concluding discussion. We set up a multi-ring Couette device that uses small basal friction to drive a 2D granular medium in a way that maintains a linear shear strain profile until the system becomes jammed, allowing us to probe the jamming transition close to $\phi_{SJ}$. The set-up subsequently shears the jammed system using the boundary racks, allowing a study of the yield stress curve for a wide range of packing fractions. Finally, reversing the direction of the drive allows us to distinguish shear-jammed (SJ) from fragile (F) states.

We systematically measured the phase boundaries in the jamming phase diagram, including close to $\phi_{SJ}$, leading to the following key observations: (i) In our system $\phi_{SJ} \approx 0.75$, whose value may depend on the friction coefficient $\mu$, polydispersity, and particle shape, though we expect the qualitative features of the jamming phase diagram to be the same. (ii) The SJ strain $\gamma_{SJ}$ is well fit by a stretched logarithmic function of $\phi$. The measured exponent $\alpha = 0.68 \pm 0.11$ is in quantitative agreement with the exponent $\alpha = 1/1.37 \approx 0.73$ measured from simulation of sheared 3d frictionless soft spheres [13]. The same form, but with $\alpha = 1$, has also been observed in experiments on shear-thickening suspensions [5]. (iii) We observe fragile states below $\phi_{SJ}$, which are not included in the traditional phase diagram [6]. In our system, small basal friction forces and particle deformability may be crucial for stabilizing the fragile force network. (iv) On the yield stress curve, for increasing packing fraction, we find that $P_{yJ}$ has an inflection point at $\phi_{SJ}$ and that $\rho_{sr,J}$ and $f_{nr,J}$ all show a change of slope near $\phi_{SJ}$, suggesting a physical transition in the nature of the steady states.

We also find that the quasi-static steady flow field changes from the non-localized basal profile for systems with $\phi < \phi_F \approx 0.7$ to a localized shear band for $\phi > \phi_c \approx 0.78$, where $\phi_F < \phi_{SJ} < \phi_c$. The coexistence of a solid and fluid phase in slowly sheared dense granular matter has been reported in many systems [24, 26, 27, 41–44]. In this work we characterize the contact network associated with the different quasi-static steady flow regimes. When $\phi = \phi_c$, the steady states have $\rho_{st} \approx 0.05$ and $f_{nr,st} \approx 1$, showing a nearly isotropic, fully percolated contact network. Notably, $\phi_c \approx \phi_c^\mu$ with $\mu \approx 0.9$, where $\phi_c^\mu$ is the isotropic jamming packing fraction with friction coefficient $\mu$ [45]. We also note that $Z_{nr,st}(\phi_{SJ}) \approx 3.4$, similar to the mean contact number observed when a strong force network percolates in both principal directions in biaxial experiments [6], and $Z_{nr,st}(\phi_c) \approx 3.9$, close to the isotropic value for ideal frictionless disks [40, 46].

The results suggest several directions for further study. First, our shear device can generate other basal profiles [33] to study how shear jamming affects the granular rheology for shear fields found in real world applications. Second, the set-up can create a controlled shear band, providing a new technique to study the generation and evolution of shear bands in dense granular flow.
