Abstract. A search for high-energy neutrinos coming from the direction of the Sun has been performed using the data recorded by the ANTARES neutrino telescope during 2007 and 2008. The neutrino selection criteria have been chosen to maximize the selection of possible signals produced by the self-annihilation of weakly interacting massive particles accumulated in the centre of the Sun with respect to the atmospheric background. After data unblinding, the number of neutrinos observed towards the Sun was found to be compatible with background expectations. The 90% CL upper limits in terms of spin-dependent and spin-independent WIMP-proton cross-sections are derived and compared to predictions of two supersymmetric models, CMSSM and MSSM-7. The ANTARES limits are comparable with those obtained by other neutrino observatories and are more stringent than those obtained by direct search experiments for the spin-dependent WIMP-proton cross-section in the case of hard self-annihilation channels (W⁺W⁻, τ⁺τ⁻).

1 Introduction

There is compelling evidence from cosmology and astrophysics that about 83% of the matter in the Universe is non-baryonic, non-relativistic and does not interact electromagnetically — the so-called dark matter [1, 2]. Much of this evidence comes from the internal dynamics of galaxy clusters [3], the rotation curves of galaxies [4], the observations from weak lensing (1E0657 − 558) [5], but also from the Cosmic Microwave Background (CMB), the large scale structure formation and type Ia supernovae. The determination of the relic density of cold dark matter (CDM) in the Universe is $\Omega_{CDM} h^2 = 0.1120 \pm 0.0056$ using observations of the CMB [6]. A popular hypothesis is that dark matter is made of Weakly Interacting Massive Particles (WIMPs) that are embedded in the visible baryonic part of galaxies and surround them in the form of a halo. There are a variety of candidates for WIMPs, among which those provided by theories based on supersymmetry (SUSY) attract a great deal of interest. In some classes of the minimal supersymmetric extension of the Standard Model (MSSM), the lightest supersymmetric particle (LSP) is stable thanks to the conservation of R-parity that forbids its decay to standard particles. Consequently, the LSP can only annihilate in pairs, making it a good WIMP candidate for dark matter [7, 8]. In these models, high-energy neutrinos are produced from the decay of the LSPs’ self-annihilation products. Two simplified versions of the MSSM model are considered in this paper, the constrained MSSM (CMSSM) [9] and the low-energy phenomenological model MSSM-7 [10]. Both have a neutralino as the LSP.

The search for WIMPs can be performed either directly by recording the recoil energy of nuclei when WIMPs scatter off them in suitable detectors, or indirectly. The indirect approach, which is adopted here, exploits a radiation signature (gamma-ray, synchrotron, positron, anti-proton or neutrino flux) produced by the self-annihilations of WIMPs accumulated in astrophysical objects such as the galactic halo, the Sun or the Earth [11].

For the case of the Sun, dealt with in the paper, WIMPs can scatter elastically and become gravitationally trapped in its core. Here, the self-annihilation rate reaches a maximum when in equilibrium with the capture rate over the age of the Solar System [12]. The WIMPs self-annihilate to Standard Model (SM) particles whose decay or hadronisation give rise to the production of energetic neutrinos which can escape from the Sun and be detected by neutrino telescopes on the Earth. The accumulation of WIMPs in the Sun must have taken place during a large period of time and therefore a very wide region in the Galaxy must...
have contributed, thereby reducing the dependence of the overall capture on the detailed sub-structures of the dark matter halo distribution. Moreover, high-energy neutrinos (above several GeV) coming from the Sun could not be explained by other known astrophysical processes.

In this paper an indirect search for dark matter by looking for high-energy neutrinos coming from the Sun, using the 2007-2008 data recorded by the ANTARES neutrino telescope, is reported. The layout of the paper is as follows. In section 2, the main features of the ANTARES neutrino telescope and the reconstruction algorithm used in this work are described. In section 3, the Monte Carlo simulation of the WIMP signal, the background expected from atmospheric muons and neutrinos, and the grid scan performed to explore the parameter space of the CMSSM and MSSM-7 models are reported. In section 4, the method used to optimise the selection of the neutrino events is described. Finally, the results obtained are discussed in section 5, where limits on the neutrino flux are derived from the absence of a signal coming from the Sun’s direction. The corresponding limits on the spin-dependent and the spin-independent WIMP-proton cross-sections are obtained and compared to the predictions of the CMSSM and MSSM-7 theoretical models.

2 The ANTARES neutrino telescope

ANTARES is the first undersea neutrino telescope and the largest of its kind in the Northern Hemisphere [13]. It is located between 2475 m (seabed) and 2025 m below the Mediterranean Sea level, 40 km offshore from Toulon (France) at 42°48’ N and 6°10’ E. The telescope consists of 12 detection lines with 25 storeys each. A standard storey includes three optical modules (OMs) [14] each housing a 10-inch photomultiplier [15] and a local control module that contains the electronics [16, 17]. The OMs are orientated 45° downwards in order to optimise their acceptance to upgoing light and to avoid the effect of sedimentation and biofouling [18]. The length of a line is 450 m and the horizontal distance between neighbouring lines is 60-75 m. In one of the lines, the upper storeys are dedicated to a test system for acoustic neutrino detection [19]. Similar acoustic devices are also installed in an additional line that contains instrumentation aimed to measure environmental parameters [20]. The location of the active components of the lines is known better than 10 cm by a combination of tiltmeters and compasses in each storey and a series of acoustic transceivers (emitters and receivers) in certain storeys along the line and surrounding the telescope [21]. A common time reference is maintained in the full detector by means of a 25 MHz clock signal broadcast from shore. The time offsets of the individual optical modules are determined in dedicated calibration facilities onshore and regularly monitored in situ by means of optical beacons distributed at various points of the apparatus which emit short light pulses through the water [22]. This allows to reach a sub-nanosecond accuracy on the relative timing [23]. Additional information on the detector can be found in Reference [13].

A high-energy muon (anti-)neutrino interacts in the matter below the detector producing a relativistic muon that can travel hundreds of metres and cross the detector or pass nearby. This muon induces Cherenkov light when travelling through the water, which is detected by the OMs. From the time and position information of the photons provided by the OMs, the direction of the muon is reconstructed and is well correlated to the neutrino direction.

Data taking started with the first 5 lines of the detector installed in 2007. The full detector was completed in May 2008 and has been operating continuously ever since, except for some periods in which repair and maintenance operations have taken place. Other physics results using this data-taking period can be found elsewhere [24-26].
A muon track is reconstructed from the position and time of the hits of the Cherenkov photons in the OMs. The reconstruction algorithm [27] is based on the minimisation of a \( \chi^2 \)-like quality parameter, \( Q \), which uses the differences between the expected and measured times of the detected photons plus a correction term that takes into account the effect of light absorption:

\[
Q = \sum_{i=1}^{N_{\text{hit}}} \left( \frac{(t_{\gamma} - t_i)^2}{\sigma_i^2} + \frac{A(a_i)D(d_{\gamma})}{<a>_0} \right),
\]

where \( t_{\gamma} \) and \( t_i \) are respectively the expected and recorded arrival time of the photons from the track, and \( \sigma_i^2 \) is the timing variance. The second term takes into account the accumulation of high charges in storeys close to the track. This term uses the measured hit charge, \( a_i \), the average hit charge calculated from all hits which have been selected for the fit, \( <a>_0 \), and the calculated photon travel distance, \( d_{\gamma} \), together with a normalisation value, \( d_{\gamma} \). The functions \( A(a_i) \) and \( D(d_{\gamma}) \) are discussed at length in Reference [27].

Depending on the configuration of the detector (see section 4) and the muon (anti-) neutrino energy, this algorithm yields an angular resolution on the upgoing neutrino direction between 1 and 7.8 degrees as illustrated by the figure 1.

3 Signal and background simulation

The flux of neutrinos as a function of their energy arriving at the Earth’s surface from the Sun’s core is computed using the software package WimpSim [28] without theoretical assump-
tions concerning the dark matter model. The neutrinos resulting from the self-annihilation channels were simulated for 16 different WIMP masses in the range from 50 GeV to 10 TeV.

Three main self-annihilation channels are chosen as benchmarks for the lightest neutralino, $\tilde{\chi}_1^0$, namely: a soft neutrino channel, $\tilde{\chi}_1^0\tilde{\chi}_1^0 \rightarrow b\bar{b}$, and two hard neutrino channels, $\tilde{\chi}_1^0\tilde{\chi}_1^0 \rightarrow W^+W^-$ and $\tilde{\chi}_1^0\tilde{\chi}_1^0 \rightarrow \tau^+\tau^-$. As the region in the SUSY parameter space determines which of these three channels is dominant, a 100% branching ratio is assumed for all of them in order to explore the widest theoretical parameter space [29–33]. The distribution of the number of muon neutrinos, $dN_\nu/dz$, arriving at the Earth per pair of WIMPs self-annihilating in the Sun’s core as a function of the energy ratio, $z = E_\nu/M_{\text{WIMP}}$, is shown in figure 2 (top) for the channels $b\bar{b}$, $W^+W^-$ and $\tau^+\tau^-$ (equivalent spectra are determined for muon antineutrinos). In this simulation, oscillations among the three neutrino flavours (both in the Sun and during their flight to Earth) are taken into account, as well as $\nu$ absorption and $\tau$ lepton regeneration in the Sun’s medium.

The main backgrounds for cosmic neutrinos in a neutrino telescope are atmospheric muons and neutrinos, both produced in the interactions of cosmic rays with the Earth’s atmosphere. Downgoing atmospheric muons dominate the trigger rate, which ranges from 3 to 10 Hz depending on the exact trigger conditions. They are simulated using Corsika [34]. Upgoing atmospheric neutrinos, which are recorded at a rate of $\sim 50 \mu$Hz (about four per day), are simulated according to the parameterisation of the atmospheric $\nu_\mu$ flux from Reference [35] in the energy range from 10 GeV to 10 PeV. The Cherenkov light produced in the vicinity of the detector is propagated taking into account light absorption and scattering in sea water [36]. The angular acceptance, quantum efficiency and other characteristics of the PMTs are taken from Reference [14] and the overall geometry corresponds to the different layouts of the ANTARES detector during each data-taking period.

A source of background specific to this search is due to the interaction of cosmic rays with the Sun’s corona. The interaction products may give rise to neutrinos in their decay. Using a simple parameterisation of the estimated $\nu_\mu$ flux from Reference [37] in the energy range from 10 GeV to 10 PeV, this background is found to amount to less than 0.4 % of the total atmospheric background in the direction of the Sun and therefore neglected.

To reduce the background from atmospheric muons, only upgoing events occurring during a period in which the Sun was below the horizon are kept. The residual contamination from misreconstructed downgoing muons is reduced using the quality parameter from Equation 2.1. Given the good agreement between data and simulated events as illustrated in figure 3, the simulated effective area is used to evaluate the expected signal (see section 4). The expected background is estimated from the scrambled data (randomising the UTC time of the selected events) in order to minimise the effect of systematic uncertainties from the simulation.

4 Optimisation of the event selection criteria

The data set used in this analysis comprises a total of 2693 runs recorded between the 27th of January 2007 and the 31st of December 2008, corresponding to a total livetime of 294.6 days, without taking into account the period in which the Sun was below the horizon. The detector consisted of 5 lines for most of 2007 and of 9, 10 and 12 lines during 2008, with a corresponding total livetime of 134.6, 38.0, 39.0 and 83.0 days respectively.

Only upgoing events are kept in the analysis. The track fit is required to use a number of hits greater than five in at least two lines in order to ensure a non-degenerate 5-parameter fit with an accurate reconstruction of the azimuth angle.
Figure 2. Top: distribution of the number of muon neutrinos at the surface of the Earth as a function of their energy normalised to the WIMP mass for the channels: $b\bar{b}$ (green), $W^+W^-$ (blue), $\tau^+\tau^-$ (red) for a WIMP mass $M_{\text{WIMP}} = 350$ GeV, as an example. Bottom: examples of the averaged effective area $\bar{A}_{\text{eff}}(M_{\text{WIMP}})$ for the signal of WIMP self-annihilation inside the Sun, $b\bar{b}$ (green), $W^+W^-$ (blue) and $\tau^+\tau^-$ (red) channels. The detector is in a 12 line configuration and $(Q_{\text{cut}}, \Psi_{\text{cut}}) = (1.4, 3^\circ)$.

The UTC time of the events is uniformly randomised in the data-taking period in order to estimate the background in the Sun’s direction from the data itself. The zenith and azimuth angles of the reconstructed tracks are kept so as to preserve the angular response of the detector in the optimisation of the selection criteria. This procedure provides a means
Figure 3. Distribution of the track fit quality parameter, Q. The blue and red dashed lines are, respectively, the expectations for atmospheric neutrino and muon events according to simulation and the black crosses are the 2007-2008 data.

The values of the parameters used in the event selection criteria, the quality parameter, Q (see Equation 2.1), and the angular separation between tracks and the Sun’s direction, Ψ, are chosen so as to optimise the model rejection factor [38]. For each WIMP mass and each annihilation channel, the chosen individual values Q_{cut} and Ψ_{cut} are those that minimise the average 90% confidence level (CL) upper limit on the ν_µ + ¯ν_µ flux, $\Phi_{\nu_\mu + \bar{\nu}_\mu}$, defined as

$$\Phi_{\nu_\mu + \bar{\nu}_\mu} = \bar{\mu}_{90\%} \sum_i A_{\text{eff}}^i(M_{\text{WIMP}}) \times T_{\text{eff}}^i,$$

(4.1)

where the index i denotes the periods with different detector configurations (5, 9, 10 and 12 detection lines), $\bar{\mu}_{90\%}$ is the average upper limit of the background at 90% CL computed using a Poisson distribution in the Feldman-Cousins approach [39] (for consistency in the comparison with other neutrino experiments limits computation) and $T_{\text{eff}}^i$ is the total live-time for each detector configuration. The effective area averaged over the neutrino energy, $A_{\text{eff}}^i(M_{\text{WIMP}})$, is defined as:

$$A_{\text{eff}}^i(M_{\text{WIMP}}) = \sum_{\nu, \bar{\nu}} \left( \int_{E_{\text{th}}}^{M_{\text{WIMP}}} A_{\text{eff}}^i(E_{\nu, \bar{\nu}}) \frac{dN_{\nu, \bar{\nu}}}{dE_{\nu, \bar{\nu}}} dE_{\nu, \bar{\nu}} \right),$$

(4.2)

where $E_{\text{th}}^{\nu} = 10 \text{ GeV}$ is the energy threshold for neutrino detection in ANTARES, $M_{\text{WIMP}}$ is the WIMP mass, $dN_{\nu, \bar{\nu}}/dE_{\nu, \bar{\nu}}$ is the energy spectrum of the (anti-)neutrinos at the surface.
of the Earth as shown in figure 2 (top), and $A_{\text{eff}}(E_{\nu,p})$ is the effective area of ANTARES as a function of the (anti-)neutrino energy for tracks coming from the direction of the Sun below the horizon. Due to their different cross-sections, the effective areas for neutrinos and anti-neutrinos are slightly different and therefore are considered separately. In addition, the fluxes of muon neutrinos and anti-neutrinos from the Sun are different and are convoluted with their respective efficiencies.

An example of an averaged effective area $\bar{A}_{\text{eff}}(M_{\text{WIMP}})$ for this analysis is shown in figure 2 (bottom) for $(Q_{\text{cut}},\Psi_{\text{cut}}) = (1.4, 3^\circ)$ with the visibility of the Sun taken into account, and a detector in a 12 line configuration. Whilst the values for each configuration of the detector are detailed in tables 1 and 2 for optimised $(Q_{\text{cut}},\Psi_{\text{cut}})$ (see section 4). The corresponding $\bar{A}_{\text{eff}}(M_{\text{WIMP}})$ distribution of the $W^+W^-$ channel is kinematically allowed for $M_{\text{WIMP}} > M_W = 80.4$ GeV [2]. Note that even though the sensitivity $\bar{A}_{\text{eff}}(M_{\text{WIMP}})$ decreases rapidly with a decreasing WIMP mass, the low mass region, $50$ GeV $< M_{\text{WIMP}} < 100$ GeV, can still be probed.

The cut optimisation procedure provides a pair of optimised values, $Q$ and $\Psi$, for each mass of the WIMP and for each studied channel. A value of $Q_{\text{cut}} = 1.4$ is found optimum

| $M_{\text{WIMP}}$ (GeV) | Channel | $\bar{A}_{\text{eff}}^{\nu_L}(M_{\text{WIMP}})$ (m$^2$) | $\bar{A}_{\text{eff}}^{\nu_R}(M_{\text{WIMP}})$ (m$^2$) | $\bar{A}_{\text{eff}}^{1}\nu(\rho)(M_{\text{WIMP}})$ (m$^2$) | $\bar{A}_{\text{eff}}^{1}\nu(\tau)(M_{\text{WIMP}})$ (m$^2$) |

Table 1. Detailed numerical values of the averaged effective areas $\bar{A}_{\text{eff}}(M_{\text{WIMP}})$ for the signal of WIMP self-annihilation inside the Sun, $b\bar{b}$, $W^+W^-$ and $\tau^+\tau^-$ channels. The 5, 9, 10 and 12 line configurations (i index) with $(Q_{\text{cut}},\Psi_{\text{cut}})$ after optimisation (see section 4) are considered. The total averaged effective area $\bar{A}_{\text{eff}}(M_{\text{WIMP}}) = \sum A_{\text{eff}}(M_{\text{WIMP}}) \times T_{\text{eff}}$ (see Equation 4.2) is reported in tables 5 and 6. Results for $M_{\text{WIMP}} > 350$ GeV are available in table 2.
for all considered masses and channels. The distribution of the optimal angular separation around the Sun, $\Psi_{\text{cut}}$, as a function of the WIMP mass is shown in figure 4. As the $bb$ channel has a softer energy spectrum, $\Psi_{\text{cut}}$ is larger for this channel. For all the channels, $\Psi_{\text{cut}}$ is larger in the low mass regime because of a worse angular resolution at low energy ($E_\nu < 100\,\text{GeV}$). After the optimised $Q_{\text{cut}}$ and $\Psi_{\text{cut}}$ are fixed, the data sample is unblinded.

5 Results and discussion

Figure 5 shows the distribution of the angular separation between the events and the Sun’s direction obtained after applying the selection criteria on the zenith angle, the minimum number of hits and lines, and a $Q_{\text{cut}} = 1.4$. A total of 27 events are found within a $20^\circ$ angular separation. No statistically significant excess is observed above the scrambled background in the Sun’s direction.

Using the values for the cuts obtained in the optimisation procedure, 90% CL limits on the $\nu_\mu + \bar{\nu}_\mu$ flux, $\Phi_{\nu_\mu} + \Phi_{\bar{\nu}_\mu}$, can be computed from the data according to Equation 4.1, where the $\mu^{90\%}$ average 90% CL upper limit is replaced by the upper limit at 90% CL, $\mu^{90\%}$, on
Figure 4. Optimum angular separation $\Psi_{\text{cut}}$ between the muon tracks and the Sun’s direction for $Q_{\text{cut}} = 1.4$ as a function of the WIMP mass for the self-annihilation channels $bb$ (green), $W^+W^-$ (blue) and $\tau^+\tau^-$ (red).

Figure 5. Differential distribution of the angular separation $\Psi$ of the event tracks with respect to the Sun’s direction for the expected background (solid blue line) compared to the data (black triangles). A 1\sigma Poisson uncertainty is shown for each data point.
Table 3. Range of parameters scanned for the CMSSM and MSSM-7 models.

| Model   | Parameter                               | Range                                    |
|---------|-----------------------------------------|------------------------------------------|
| CMSSM   | Common scalar mass                      | $50 \text{ GeV} < m_0 < 4 \text{ TeV}$  |

|         |   generation squarks                    |                                          |

the number of observed events. The corresponding limits are presented in figure 6 (top) for the three representative self-annihilation channels $b\bar{b}$, $W^+W^-$ and $\tau^+\tau^-$. Given its soft energy spectrum (see figure 2 (top)), the channel $b\bar{b}$ yields the weakest limit, while the others ($W^+W^-$, $\tau^+\tau^-$) are the most stringent.

The corresponding limits on the muon flux are calculated using a conversion factor between the neutrino and the muon fluxes ($\Phi_\mu = \Gamma_{\nu \rightarrow \mu} \times \Phi_{\nu + \bar{\nu}}$) computed using the package DarkSUSY [40]. Figure 6 (bottom) shows the 90% CL muon flux limits, $\Phi_\mu$, for the channels $b\bar{b}$, $W^+W^-$ and $\tau^+\tau^-$. The latest results from Baksan [41], Super-Kamiokande [42] and IceCube-79 [43] are also shown for comparison.

Assuming equilibrium between the WIMP capture and self-annihilation rates in the Sun, the limits on the spin-dependent (SD) and the spin-independent (SI) WIMP-proton scattering cross-sections are derived for the case in which one or the other is dominant.

The Sun is considered to be free in the galactic halo [44]. A local dark matter density of 0.3 GeV/cm$^3$ and a Maxwellian velocity distribution of the WIMP with a RMS velocity of 270 km/s are assumed [2], and no additional dark matter disk that could enhance the local dark matter density is considered (see Reference [45] for a discussion).

The 90% CL limits for the SD, $\sigma_{p,SD}$, and SI, $\sigma_{p,SI}$, WIMP-proton cross-sections derived for the signal channels $b\bar{b}$, $W^+W^-$ and $\tau^+\tau^-$ are presented in figure 7. The latest results from Baksan [41], Super-Kamiokande [42] and IceCube-79 [43] together with the latest and the most stringent limits from the direct search experiments SIMPLE [46], COUPP [47] and XENON100 [48] are shown. The allowed parameter space from the CMSSM and MSSM-7 models according to the results from an adaptative grid scan performed with DarkSUSY are also shown. For CMSSM and MSSM-7, their free parameters are limited as shown in table 3. All the limits presented in figure 7 are computed with a muon energy threshold at $E_\mu = 1$ GeV. For this figure the shaded regions show a grid scan of the model parameter space, taking into account the latest constraints for various observables from accelerator-based experiments shown in table 4, in particular the results on the Higgs boson mass from ATLAS and CMS, $M_h = 125 \pm 2$ GeV [49], and the latest limit on the SI WIMP-proton scattering cross-section by XENON100 [48]. A relatively loose constraint on the neutralino relic density $0 < \Omega_{\chi_c} h^2 < 0.1232$ [6] is used to take into account the existence of other possible types of dark matter particles.

All the results are summarised in tables 5 and 6, where for each WIMP mass and channel the values of the optimised angular separation, the average 90% CL upper limit computed from the background without signal expectation, the 90% CL upper limit on the number of observed events, the total averaged effective area and the 90% CL upper limits are
Observable | Lower limit (95% CL)

Table 4. Summary of the observables used in the grid scan performed with the package DarkSUSY on the CMSSM and MSSM-7 free parameter space. **Top:** observables for which only limits currently exist. The mass of the chargino \(\tilde{\chi}^\pm_1\), gluino \(\tilde{g}\), squarks \(\tilde{q}\), sleptons \(\tilde{e}_L, \tilde{e}_R, \tilde{\mu}_{L,R}\), sneutrinos \(\tilde{\nu}\), neutralinos \(\tilde{\chi}^0_i\) (LSP and dark matter candidate in this analysis), \(\tilde{\chi}^0_2, \tilde{\chi}^0_3\) and \(\tilde{\chi}^0_4\), charged Higgs \(H^\pm\) and the effective neutrino coupling \(g_{\nu l}\) from invisible Z-decay width [2]. **Bottom:** observables for which a measurement is available. The Higgs boson \(h\) mass as an averaged result from CMS and ATLAS Collaborations [49], the discrepancy \(\delta \alpha_{\mu}^{\text{SUSY}}\) between the experimental value and the SM prediction of the anomalous magnetic moment of the muon \((g - 2)_\mu\) [2] and the branching ratio of the b-hadron decay \(B \rightarrow X_s \gamma\) [2].

Presented. Systematic uncertainties are taken into account and included in the evaluation of the limits using the PoLe software following the approach detailed in Reference [50]. The total systematic uncertainty on the detector efficiency is around 20% and comes mainly from the uncertainties on the average quantum efficiency of the PMTs as well as the angular acceptance and the sea water absorption length (\(\pm 10\%\) for all of them). The detailed uncertainties study is described in Reference [23]. This total systematic uncertainty translates into a degradation of the upper limit between 3% and 6%, depending on the WIMP mass.

The neutrino flux due to WIMP annihilation in the Sun is highly dependent on the capture rate of WIMPs in the core of the Sun, which in turn is dominated by the SD WIMP-proton cross-section. This makes these indirect searches better compared to direct search experiments. This is not the case for the SI WIMP-proton cross-section, where the limits coming from direct search experiments like XENON100 are better thanks to their target materials.

Using the first two years of data recorded by the ANTARES neutrino telescope, an indirect search for dark matter towards the Sun has been performed. The observed number of neutrino events in the Sun’s direction is compatible with the expectation from the atmospheric backgrounds. The derived limits are comparable with those obtained by other neutrino observatories and are more stringent than those obtained by direct search experiments for the spin-dependent WIMP-proton scattering cross-section thanks to the hard channels \((W^+W^−, \tau^+\tau^-)\). The present ANTARES limits already begin to constrain the parameter spaces of the MSSM-7 model.
Figure 6. Top: 90% CL upper limits on the neutrino plus anti-neutrino flux as a function of the WIMP mass in the range $M_{\text{WIMP}} \in [50 \text{ GeV}; 10 \text{ TeV}]$ for the three self-annihilation channels $b\bar{b}$ (green), $W^+W^-$ (blue), $\tau^+\tau^-$ (red). Bottom: 90% CL upper limit on the muon flux as a function of the WIMP mass in the range $M_{\text{WIMP}} \in [50 \text{ GeV}; 10 \text{ TeV}]$ for the three self-annihilation channels $b\bar{b}$ (green), $W^+W^-$ (blue) and $\tau^+\tau^-$ (red). The results from Baksan 1978 – 2009 [41] (dash-dotted lines), Super-Kamiokande 1996 – 2008 [42] (dotted lines) and IceCube-79 2010 – 2011 [43] (dashed lines) are also shown.
Figure 7. 90% CL upper limits on the SD and SI WIMP-proton cross-sections (upper and lower plots, respectively) as a function of the WIMP mass, for the three self-annihilation channels: $bb$ (green), $W^+W^-$ (blue) and $\tau^+\tau^-$ (red), for ANTARES 2007-2008 (solid line) compared to the results of other indirect search experiments: bakas 1978 – 2009 [41] (dash-dotted lines), Super-Kamiokande 1996 – 2008 [42] (dotted lines) and IceCube-79 2010 – 2011 [43] (dashed lines) and the result of the most stringent direct search experiments (black): sIMPLE 2004 – 2011 [46] (short dot-dashed line in upper plot), COUPP 2010 – 2011 [47] (long dot-dashed line in upper plot) and XENON100 2011 – 2012 [48] (dashed line in lower plot). The results of a grid scan of the CMSSM and MSSM-7 are included (dark and light grey shaded areas respectively) for the sake of comparison.

Table 6. Results after optimisation and unblinding for the angular separation $\Psi_{\text{cut}}$, the 90% CL upper limit on the expected signal $\mu^{90\%}$, the total averaged effective area $\tilde{A}_{\text{eff}}(M_{\text{WIMP}}) = \sum_i \tilde{A}_{i,\text{eff}}(M_{\text{WIMP}}) \times T_{i,\text{eff}}$ (with $i$ corresponding to a given period of the detector), the 90% CL sensitivities on the neutrino+anti-neutrino flux at the Earth $\overline{\Phi}_{\nu_{e}+\bar{\nu}_{e}}$, and on the spin-dependent and spin-independent WIMP-proton cross-sections $\sigma_{p,\text{SD}}$ and $\sigma_{p,\text{SI}}$ respectively. Results for $M_{\text{WIMP}} < 500$ GeV are available in table 5.
Acknowledgments

The authors acknowledge the financial support of the funding agencies: Centre National de la Recherche Scientifique (CNRS), Commissariat à l’énergie atomique et aux énergies alternatives (CEA), Agence National de la Recherche (ANR), Commission Européenne (FEDER fund and Marie Curie Program), Région Alsace (contrat CPERS), Région Provence-Alpes-Côte d’Azur, Département du Var and Ville de La Seyne-sur-Mer, France; Bundesministerium für Bildung und Forschung (BMBF), Germany; Istituto Nazionale di Fisica Nucleare (INFN), Italy; Stichting voor Fundamenteel Onderzoek der Materie (FOM), Nederlandse organisatie voor Wetenschappelijk Onderzoek (NWO), the Netherlands; Council of the President of the Russian Federation for young scientists and leading scientific schools supporting grants, Russia; National Authority for Scientific Research (ANCS), Romania; Ministerio de Ciencia e Innovación (MICINN), Prometeo of Generalitat Valenciana and MultiDark, Spain; Agence de l’Oriental and CNRST, Morocco. We also acknowledge the technical support of Ifremer, AIM and Foselev Marine for the sea operation and the CC-IN2P3 for the computing facilities.
