LTL specification

A B S T R A C T

This paper proposes a method to synthesise controllers for systems with possibly infinite number of states that satisfy a specification given as an LTL formula. A common approach to handle this problem is to first compute a finite-state abstraction of the original state space and then synthesise a controller for the abstraction. This paper proposes to use an abstraction method called divergent stutter bisimulation to abstract the state space of the system. As divergent stutter bisimulation factors out stuttering steps, it typically results in a coarser and therefore smaller abstraction, at the expense of not preserving the temporal “next” operator. The paper leverages results about divergent stutter bisimulation from model checking and shows that divergent stutter bisimulation is a sound and complete abstraction method when synthesising controllers subject to specifications in LTL.

1. Introduction

Dynamic system models are often used for safety-critical applications, where formal verification and synthesis are of great importance (Belta et al., 2017). This paper is concerned with controller synthesis, where the control logic is automatically computed from a model of the system with possibly infinite number of states and a specification of the desired behaviour in temporal logic. In this context, the state space is typically abstracted and partitioned to produce a finite transition system, and then finite-state machine synthesis methods are applied (Kloetzer & Belta, 2008; Ramadge, 1989).

The most commonly used abstraction method for this purpose is bisimulation (Milner, 1989). Bisimulation is a strong behavioural equivalence of transition systems, which preserves all temporal logic properties (Baier & Katoen, 2008). There exist polynomial-time algorithms to calculate a bisimilar abstraction of a finite-state system (Fernandez, 1990). Bisimulation can also be applied to continuous state spaces (Belta et al., 2017; Megawati & van der Schaft, 2016; Pappas, 2003), but the bisimulation algorithms are only guaranteed to terminate for specific classes of continuous systems (Alur et al., 2000).

To overcome these difficulties, the literature proposes various alternatives to bisimulation. Approximate bisimulation relaxes bisimulation by allowing a bounded mismatch between the behaviours of the abstract and concrete system (Girard & Pappas, 2007). A further relaxation is obtained by considering (approximate) simulation and feedback refinement relations. These are sound but not necessarily complete abstraction methods, in the sense that the nonexistence of a controller for the abstract system does not imply the nonexistence of a controller for the concrete system (Belta et al., 2017; Reissig et al., 2016; Tabuada, 2009; Zamani et al., 2011). Dual-simulation (Wagenmaker & Ozay, 2016) produces a coarser abstraction than bisimulation; it uses overlapping subsets rather than quotient sets. Moreover, the dual-simulation algorithm avoids the set difference operation, so that it preserves the convexity of the regions in the abstracted state space. Unlike bisimulation, it does not preserve all temporal logic properties, but it preserves the results of controller synthesis when applied to linear temporal logic (LTL).

Bisimulation and its variants consider all transitions as significant. The potential for abstraction can be increased by factoring out so-called stuttering steps where the system remains in the same region of the state space without changing any of the propositions relevant for the specification. By combining sequences of stuttering steps with the next non-stuttering step in a single transition, a coarser abstraction is produced. However,
the temporal “next” operator is no longer preserved because the number of steps between two states may change. Accordingly, over-approximations (Liu et al., 2013; Nilsson et al., 2017) have been proposed to synthesise controllers for continuous-time systems. The approach is sound for specifications in LTL, the LTL fragment without the “next” operator, but not complete in general.

This paper considers another approach to factor out stuttering steps, called divergent stutter bisimulation (Baier & Katoen, 2008). Divergent stutter bisimulation preserves CTL\(\L^*\), the fragment of the Computation Tree Logic CTL without the “next” operator (Baier & Katoen, 2008). An efficient algorithm to compute abstractions based on divergent stutter bisimulation exists and has been used to simplify state spaces (Groote et al., 1997; Groote & Vaandrager, 1990). Once an abstraction and a quotient system are constructed using divergent stutter bisimulation, verification can be done using existing tools (Baier & Katoen, 2008; Clarke et al., 2004) and gives the same result as for the original system. Yet, synthesis is more difficult, because it is not immediately clear how a controller synthesised for the abstracted system can be used to control the original system. A single transition of the abstract controller has to be implemented by a sequence of several transitions (including stuttering steps) in the original system.

This paper shows that divergent stutter bisimulation is a sound and complete abstraction method when synthesising for specifications in LTL. It is shown that a controller for the abstracted system exists if and only if such a controller exists for the original system with possibly infinite number of states, and it is shown how the controller for the original system can be constructed from the abstract controller.

The divergent stutter bisimulation algorithm and the algorithm to construct a controller for the original system from the abstract controller have been implemented in TuLiP (Filiot et al., 2016) and applied to discrete-time linear systems from Hussenin and Tabuada (2018) and Wagenmaker and Ozay (2016). It is shown that the abstracted system from divergent stutter bisimulation is smaller compared to bisimulation. As expected, lifting the control from the discrete abstraction to the original system is more laborious than it would be using only bisimulation.

This paper is organised as follows. Section 2 gives a brief background on modelling and linear temporal logic and abstraction. Next, Section 3 explains divergent stutter bisimulation and reviews the algorithm to partition a state space while preserving divergent stutter bisimulation. Section 4 shows how the abstracted controller is used to construct a controller for the original system and proves that the abstraction method is sound and complete. Section 5 applies the algorithm to examples, and Section 6 gives concluding remarks.

2. Preliminaries

This section gives a brief overview of notations used throughout the paper. Most of the following definitions are adopted from Baier and Katoen (2008).

2.1. Finite and infinite strings

Let X be a set. The sets of finite and infinite strings of symbols from X are denoted by \(X^*\) and \(X^\infty\), respectively. The combined set of finite and infinite strings over X is \(X^\infty = X^* \cup X^\infty\). The empty string is \(\epsilon \in X^*\), and the set of nonempty finite strings is \(X^+ = X^* \setminus \{\epsilon\}\). The concatenation of strings \(s \in X^*\) and \(t \in X^\infty\) is written as \(st\). The notation \(s^k\) refers to the string obtained by concatenating \(k \geq 0\) copies of string \(s \in X^*\). A string \(s \in X^*\) is called a prefix of \(t \in X^\infty\), written \(s \subseteq t\), if there exists \(u \in X^\infty\) such that \(su = t\).

An infinite ascending sequence \(s_0 \subseteq s_1 \subseteq s_2 \cdots\) of finite strings \(s_i \in X^*\) has a unique least upper bound \(s \in X^\infty\) with \(s_i \subseteq s\) for all \(i \geq 0\), called its closure and denoted by cl\(\{s_i \mid i \geq 0\}\). For \(s \in X^\infty\), the duplicate-free string unq\(s\) in \(X^\infty\) is obtained from \(s\) by removing all elements that are equal to their predecessor. For example, unq\(01132233\ldots\) = 01323. Removing duplicates from an infinite string may result in a finite or infinite string.

2.2. Transition systems and problem formulation

Definition 1. A transition system is a tuple \(G = (Q, Q^\infty, \rightarrow, \Pi, \models)\) where \(Q\) is a set of states, \(Q^\infty \subseteq Q\) is the set of initial states, \(Q \times Q\) is the state transition relation, \(\Pi\) is a set of atomic propositions, and \(\models \subseteq Q \times \Pi\) is the satisfaction relation. \(G\) is called finite if \(Q\) is finite.

Definition 2. A finite path fragment \(s\) in a transition system \(G = (Q, Q^\infty, \rightarrow, \Pi, \models)\) is a finite state sequence \(x_0 \cdots x_n\) such that there are transitions \(x_i \rightarrow x_{i+1}\) for all \(0 < i \leq n\). An infinite path fragment \(s\) is an infinite state sequence \(x_0x_1 \cdots\) such that \(x_{i-1} \rightarrow x_i\) for all \(0 < i\). If \(x_0 \in Q^\infty\) then the path fragment is called a path in \(G\).

A path in a transition system describes a possible behaviour of the system.

Definition 3. Let \(G = (Q, Q^\infty, \rightarrow, \Pi, \models)\) be a transition system. The labelling function \(L: Q \rightarrow 2^\Pi\) is defined by \(L(x) = \{\pi \in \Pi \mid x \models \pi\}\).

The labelling function \(L\) relates to each state \(x \in Q\) a set of atomic propositions that are satisfied by state \(x\). The labelling function \(L\) is extended to finite or infinite path fragments \(s = x_0x_1 \cdots \in Q^\infty\) by applying it to each state of the path fragment, \(L(s) = L(x_0)L(x_1)\cdots\).

This paper is concerned with the construction of controllers that restrict a transition system so that it only enters certain states.

Definition 4 (Controller). Let \(G = (Q, Q^\infty, \rightarrow, \Pi, \models)\) be a transition system. A controller for \(G\) is a function \(C: Q^\infty \rightarrow 2^Q\).

The controller takes as argument a path, representing the history of all states visited in the path. If \(x_0, \ldots, x_n \in Q\) are states \((n \geq 0)\), then the path composed of these states is written \(x_0 \cdots x_n \in Q^\infty\). The idea is that, after visiting states \(x_0, \ldots, x_n \in Q\), the controlled system is allowed to enter a state \(x_{n+1} \in Q\) if and only if \(x_{n+1} \in C(x_0 \cdots x_n)\).

Definition 5. Let \(G = (Q, Q^\infty, \rightarrow, \Pi, \models)\) be a transition system, and let \(C: Q^\infty \rightarrow 2^Q\) be a controller for \(G\). The controlled system, \(G\) under the control of \(C\), is \(C[G] = (Q, Q^\infty \cap C(\epsilon), \rightarrow_\mathcal{C}, \Pi, \models_\mathcal{C})\), where

(i) \(x_0 \cdots x_n \rightarrow_\mathcal{C} x_0 \cdots x_n x_{n+1}\) if and only if \(x_n \rightarrow x_{n+1}\) in \(G\) and \(x_{n+1} \in C(x_0 \cdots x_n)\),

(ii) \(x_0 \cdots x_n \models_\mathcal{C} \pi\) if and only if \(x_n \models \pi\).

In Definition 5, the states of the closed-loop system, \(C[G]\), are paths of \(G\) that are accepted by \(C\). The transitions of the closed-loop system have the form of \(x_1 \cdots x_n \rightarrow_\mathcal{C} x_1 \cdots x_{n+1}\), where \(x_1 \cdots x_n\) is path of \(G\) and a state of the controlled system \(C[G]\). From a state \(x_1 \cdots x_n\) of \(C[G]\), the next state \(x_1 \cdots x_{n+1}\) can be reached if \(x_n \rightarrow x_{n+1}\) is a transition in \(G\) and \(x_{n+1} \in C(x_1 \cdots x_n)\).

Accordingly, the paths in \(C[G]\) are strings of the states of \(C[G]\), i.e., strings of strings. The following definition adds a more convenient notation to also consider strings over states of \(G\) as paths in \(C[G]\).
Definition 6. Let $G = \langle Q, Q^0, \rightarrow, \Pi, \models \rangle$, and let $C$ be a
controller for $G$. A string $s \in Q^\infty$ is said to be a path in $C/G$ if
$s$ is a path in $G$, and for every prefix $rx \subseteq s$ with $r \in Q^*$ and
$x \in Q$ it holds that $x \in C(r)$.

Another important concern in the following is divergence, where a transition system stays in the same state indefinitely.

Definition 7. Let $G = \langle Q, Q^0, \rightarrow, \Pi, \models \rangle$, and let $C$ be a
controller for $G$. A state $x \in Q$ is divergent in $G$ if $x \rightarrow x$. A finite
path $s = rx$ with $r \in Q^*$ and $x \in Q$ is divergent in $C/G$ if its last
state $x$ is divergent in $G$ and $x \in C(sx^k)$ for all $k \geq 0$.

2.3. Linear temporal logic

This paper considers requirement specifications written in
Linear Temporal Logic (Baier & Katoen, 2008). Specifically, the
fragment considered is LTL$^\omega$ which does not include the next
operator $\mathcal{A}$. LTL$^\omega$ formulas $\varphi$ over the set of atomic propositions $\Pi$ are formed according to the syntax $\varphi := \pi | \varphi_1 \land \varphi_2 | \neg \varphi_1 | \varphi_1 \mathcal{U} \varphi_2$, where $\pi \in \Pi$, and $\varphi_1$ and $\varphi_2$ are LTL$^\omega$ formulas. $\mathcal{U}$ is the until operator, which is also used to define the more common
operators $\mathcal{A}$, $\mathcal{E}$, $\mathcal{P}$, $\mathcal{G}$, $\mathcal{F}$.

Definition 8. Let $G = \langle Q, Q^0, \rightarrow, \Pi, \models \rangle$ be a transition system
and let $\varphi$ be an LTL$^\omega$ formula over $\Pi$. An infinite path fragment $s \in Q^\infty$ is defined to satisfy $\varphi$, written $s \models \varphi$, recursively as follows:

- $s \models \pi$ if $s = x_0x_1 \cdots$ and $x_0 \models \pi$;
- $s \models \varphi_1 \land \varphi_2$ if both $s \models \varphi_1$ and $s \models \varphi_2$;
- $s \models \neg \varphi_1$ if $s \models \varphi_1$ does not hold;
- $s \models \varphi_1 \mathcal{U} \varphi_2$ if $s = x_0x_1 \cdots$ and there exists $k \geq 0$ such that
  $x_k \mathcal{U} x_{k+1} \cdots \models \varphi_1$ for $i = 0, \ldots, k - 1$ and $x_kx_{k+1} \cdots \models \varphi_2$.

The transition system $G$ is said to satisfy $\varphi$, written $G \models \varphi$, if $s \models \varphi$ holds for every infinite path $s$ in $G$.

According to this semantics, a transition system satisfies an
LTL$^\omega$ formula if the formula holds on every infinite path. The
definition does not cover paths that visit a deadlock state, i.e., a
state without outgoing transitions. It is common to rule out this
case so that all paths can be extended to an infinite path.

Definition 9. Let $G = \langle Q, Q^0, \rightarrow, \Pi, \models \rangle$ be a transition system.
Then $G$ is called deadlock free if, $Q^0 \neq \emptyset$ and for every reachable state $x \in Q$ there exists a state $y \in Q$ such that $x \rightarrow y$.

This paper is concerned with the synthesis problem, which is to compute a controller enforcing a specification given as an LTL$^\omega$
formula for a given transition system. This problem can now be
defined formally as follows.

Problem 1. Given a transition system $G$ and an LTL$^\omega$ formula $\varphi$,
find a controller $C$ such that $C/G$ is deadlock-free and $C/G \models \varphi$.

There are several methods to construct a controller that en-
forces an LTL$^\omega$ formula on a finite transition system. This can be
done by transforming the LTL$^\omega$ formula into a Rabin or a Büchi
automaton, taking a product of the automaton with the transition
system, and then solving the control problem using existing
methods (Kloetzer & Belta, 2008; Ramadge, 1989).

2.4. Abstraction

For systems with very large or infinite state spaces, finding a
solution to Problem 1 becomes intractable. One approach to han-
dle the synthesis problem in such cases is the use of abstraction

techniques, where the state space is partitioned to produce an
equivalent synthesis problem that can be solved more easily.

A common way to partition a transition system is to identify
and group equivalent states. Given a set $X$, a relation $\approx \subseteq X \times X$ is an equivalence relation on $X$ if it is reflexive, symmetric, and
transitive. The equivalence class of $x \in X$ is $[x] = \{ x' \in X | x \approx x' \}$, and $X/\approx = \{ [x] | x \in X \}$ is the set of all equivalence classes modulo $\approx$.

Given an equivalence relation $\approx$ on the state set $Q$ of a
transition system, a quotient transition system can be constructed
by grouping all equivalent states into a single abstract state, i.e.,
using $Q/\approx$ as a reduced state set. For the quotient transition system
to preserve liveness properties, it is important to distinguish
whether or not it is possible for the system behaviour to
remain within an equivalence class indefinitely.

Definition 10. Let $G = \langle Q, Q^0, \rightarrow, \Pi, \models \rangle$ be a transition system,
and let $\approx \subseteq Q \times Q$ be an equivalence relation. A state $x \in Q$ is
$d$-divergent in $G$ if there exists an infinite path fragment $xx_kx_2 \cdots$
in $G$ such that $x \approx x_i$ for all $i > 0$. An equivalence class $\tilde{x} \in Q/\approx$
is $d$-divergent in $G$ if it contains a $d$-divergent state.

Definition 11. Let $G = \langle Q, Q^0, \rightarrow, \Pi, \models \rangle$ be a transition system,
and let $\approx \subseteq Q \times Q$ be an equivalence relation. The divergence-
respecting quotient transition system is $G/\approx = \langle Q, Q^0, \rightarrow, \Pi, \models \rangle$
where,

- $\tilde{Q} = Q/\approx$;
- $\tilde{Q}^0 = \{ \tilde{x} \in \tilde{Q} | \tilde{x} \cap Q^0 \neq \emptyset \}$;
- $\tilde{x} \rightarrow \tilde{y}$ if $\tilde{x}$ is divergent;
- $\tilde{x} \rightarrow \tilde{y}$ for $\tilde{x} \neq \tilde{y}$, if there exist $\exists \in \tilde{x}$ and $\exists \in \tilde{y}$ such that
  $\exists \rightarrow \exists'$;
- $\tilde{x} \models \pi$ if there exists $\exists \in \tilde{x}$ such that $\exists \models \pi$.

Like a standard quotient transition system, the divergence-
respecting quotient includes a transition $\tilde{x} \rightarrow \tilde{y}$ between two
equivalence classes if the original transition system has a trans-
ition $x \rightarrow y$ between some states of these classes, and an
equivalence class satisfies a proposition if one of its states sats-
ifies that proposition. The difference to a standard quotient lies
in the treatment of selfloop transitions: a selfloop $\tilde{x} \rightarrow \tilde{x}$ is only
included in the divergence-respecting quotient if $\tilde{x}$ is a divergent
equivalence class.

For simplicity of notation, in the following, the tilde super-
scripts of the transition and satisfaction relations of quotient
transition systems will be omitted, thus identifying $\rightarrow$ with
and $\models$ with $\models$. Further, the following definition is used to relate path fragments of a transition system to those of its quotient.

Definition 12. Let $G = \langle Q, Q^0, \rightarrow, \Pi, \models \rangle$ be a transition system,
and let $\approx \subseteq Q \times Q$ be an equivalence relation. For a
(finite or infinite) path fragment $s = x_0x_1x_2 \cdots \in Q^\infty$, the term
$[s] = [x_0][x_1][x_2] \cdots \in (Q/\approx)^\infty$ denotes the path fragment of
equivalence classes that appear in $s$.

3. Stutter equivalence

This paper addresses the problem of abstracting a transition system before calculating a controller to enforce an LTL$^\omega$
specification. Without the temporal "next" operator, the logic LTL$^\omega$
cannot distinguish how often states with the same labels are
repeated. This leads to the idea of stutter equivalence (Baier &
Katoen, 2008). Transitions between states with equal labels are

\footnote{Here and in the following, $\tilde{x} \in Q/\approx$ is an unspecified equivalence class,
which may or may not be equal to the equivalence class $[x]$ containing $x$.}
called stuttering steps, and stutter bisimulation considers transition systems as equivalent if they have the same infinite paths while factoring out the stuttering steps. To preserve liveness properties, this relation is refined to divergent stutter bisimulation (Baier & Katoen, 2008).

3.1. Stutter equivalent paths

**Definition 13.** Let \( G_i = (Q_i, \rightarrow_i, \Pi_i, \models_i) \) be transition systems, and let \( s_i \) be path fragments in \( G_i \), for \( i = 1, 2 \). Then \( s_1 \) and \( s_2 \) are stutter equivalent if \( \text{uniq}(L(s_1)) = \text{uniq}(L(s_2)) \) and \( s_1 \) and \( s_2 \) are either both finite or both infinite.

According to **Definition 3**, \( L(s) \) is the sequence of labellings visited on the path fragment \( s \), and \( \text{uniq}(L(s)) \) is the same sequence after removing duplicates. Therefore, stutter equivalent paths have the same sequences of atomic propositions, while the number of states repeated by stuttering steps, i.e., transitions whose source and target states satisfy exactly the same propositions, does not need to be equal. It is known that stutter equivalent paths satisfy the same LTL\(_\land\) properties.

**Proposition 1 (Baier & Katoen, 2008).** Let \( G_i = (Q_i, \rightarrow_i, \Pi_i, \models_i) \) be transition systems, and let \( s_i \in Q_i^\omega \) be path fragments in \( G_i \), for \( i = 1, 2 \). If \( s_1 \) and \( s_2 \) are stutter equivalent, then \( s_1 \models \varphi \) if and only if \( s_2 \models \varphi \) for any LTL\(_\land\) formula \( \varphi \).

3.2. Divergent stutter bisimulation

**Definition 14.** Let \( G = (Q, \rightarrow, \Pi, \models) \) be a transition system. A relation \( \approx \subseteq Q \times Q \) is a *divergent stutter bisimulation* equivalence on \( G \) if for all \( x_1, x_2 \in Q \) such that \( x_1 \approx x_2 \) the following conditions hold:

1. \( \text{L}(x_1) = \text{L}(x_2) \).
2. If there exists \( x'_1 \in Q \) such that \( x_1 \rightarrow x'_1 \) and \( x'_1 \not\approx x_2 \) then there exists a finite path fragment \( x'_2 y_1 \cdots y_n x_2' \) such that \( n \geq 0 \) and \( x'_2 \approx x_2' \).
3. If there exists \( x'_2 \in Q \) such that \( x_2 \rightarrow x'_2 \) and \( x'_2 \not\approx x_1 \) then there exists a finite path fragment \( x_1' z_1 \cdots z_n x'_1 \) such that \( n \geq 0 \) and \( x_1 \approx z_1 \) for \( i = 1, \ldots, n \) and \( x'_2 \approx x'_1 \).
4. \( x_1 \approx \text{divergent} \) if and only if \( x_2 \approx \text{divergent} \).

Condition (i) requires that equivalent states are labelled with the same propositions, i.e., the equivalence relation is proposition-preserving. According to conditions (ii) and (iii), for two states to be considered as equivalent, if one of them reaches a state in a different equivalence class then the other must reach an equivalent state either directly or after some stuttering steps. The last condition (iv) means that two states are only equivalent if either both exhibit divergent paths or none of them does.

**Theorem 2 (Baier & Katoen, 2008).** Let \( G = (Q, \rightarrow, \Pi, \models) \) be a transition system, and let \( \approx \) be a divergent stutter bisimulation on \( G \). If \( s \in Q^\omega \) is a path in \( G \) then there exists a stutter equivalent infinite path \( \tilde{s} \) in \( G/\approx \).

**Theorem 2** shows that, if a transition system \( G \) is abstracted to a divergence-respecting quotient \( G/\approx \) with respect to a divergent stutter bisimulation, then for any infinite path in the original system \( G \) there exists a stutter equivalent infinite path in the abstraction \( G/\approx \). By **Proposition 1**, these paths satisfy the same LTL\(_\land\) properties.

3.3. Divergent stutter bisimulation algorithm

There exists a polynomial-time algorithm to calculate the coarsest divergent stutter bisimulation relation of a transition system (Groote et al., 2017; Groote & Vaandrager, 1990), which is summarised in this section. The algorithm performs partition refinement starting from an initial partition consisting of regions determined by the propositions. Regions are split repeatedly when they contain states that cannot reach the same successors. The splits are performed by calculating the sets of predecessors of a region and then intersecting all regions with this predecessor set.

**Definition 15.** Let \( G = (Q, \rightarrow, \Pi, \models) \) be a transition system. The set of predecessors of state \( x \in Q \) is \( \text{Pre}(x) = \{ y \in Q \mid y \rightarrow x \} \). The set of predecessors of a set of states \( X \subseteq Q \) is \( \text{Pre}(X) = \bigcup_{x \in X} \text{Pre}(x) \). The set of stutter predecessors of a state set \( T \subseteq Q \) within \( P \) is \( \text{PPre}(T, P) = \{ y \in P \mid \text{there exists a finite path fragment } y y_1 \cdots y_n x \text{ in } G \text{ with } n \geq 0 \text{ and } y_1, \ldots, y_n \in P \text{ and } x \in T \} \).

The set of divergent states within \( P \) is

\[
\text{Div}(P) = \{ y \in P \mid \text{there exists an infinite path fragment } y y_1 \cdots y_k y_{k+1} \cdots y_n x \text{ in } G \text{ such that } y_k \in P \text{ for all } k \geq 1 \}.
\]

The stutter predecessors of \( T \) within \( P \) are states in the region \( P \) that can reach a state in \( T \) directly or after a finite number of steps within \( P \). The divergent states within \( P \) are states from where an infinite number of transitions is possible while staying within \( P \). The sets of stutter predecessors and divergent states can be characterised as fixed points. Given the recursive definition

\[
\text{PPre}(\ast, P) = \text{Pre}(P) \cap P;
\]

\[
\text{PPre}^{i+1}(T, P) = \text{Pre}(\text{PPre}(T, P)) \cap P;
\]

it is clear that

\[
\text{PPre}(T, P) = \bigcup_{i \geq 0} \text{PPre}(i, P);
\]

\[
\text{Div}(P) = \bigcap_{i \geq 0} \text{PPre}(i, P).
\]

For finite-state systems, these state sets can be computed in a finite number of steps, but for infinite systems the calculation of \( \text{PPre}(T, P) \) or \( \text{Div}(P) \) may fail to terminate.

**Algorithm 1** uses these operations to calculate a partition that respects divergent stutter bisimulation. Line 1 computes the initial partition based on the propositions. It can be constructed as \( Q = Q/\sim \) where the relation \( \sim \subseteq Q \times Q \) is such that \( x \sim y \), if \( x \models \pi \) if and only if \( y \models \pi \) for all \( \pi \in \Pi \). Then the algorithm enters the loop, which repeatedly refines each region until all conditions in **Definition 14** are satisfied. Line 4 checks for regions to be refined based on divergence. If a region \( P \) contains both divergent and non-divergent regions, i.e., if the set \( \text{Div}(P) \) is nonempty and a proper subset of \( P \), then it is refined by putting the divergent and non-divergent states into their own regions. Additionally, line 8 checks for splits based on stutter predecessors. Here it needs to be checked for each pair of regions \( P \) and \( T \) whether some of the states in \( P \) are stutter predecessors of \( T \) while others are not, in which case \( P \) is split. The algorithm terminates when no more splits are necessary. Then the result \( Q \) represents the coarsest partition that respects divergent stutter bisimulation.
Algorithm 1: Divergent stutter bisimulation

**Input:** Transition system $\mathcal{G} = (Q, Q^\circ, \rightarrow, \Pi, \|=)$

**Output:** Coarsest partition $\tilde{Q}$

1. $\tilde{Q} \leftarrow$ Initial proposition-preserving partition;
2. $\text{done} \leftarrow$ false;
3. while $\neg \text{done}$ do

**Example 1 (Wagenmaker & Ozay, 2016).** Assume the transition relation

\[
\tau(t + 1) = 2x(t) + u(t), \tag{7}
\]

where $x(t) \in Q = [-1.5, 1.5]$ is the state, and $u(t) \in U = [-2, 2]$ is the control input. The initial partition consists of three regions, $s_1 = [-1.5, -1)$, $s_2 = [-1, 1)$, and $s_3 = [1, 1.5]$. For demonstration, consider the computation of $\text{PPre}(s_3, s_2)$ during the execution of Algorithm 1. First, $\text{PPre}^0(s_3, s_2) = \text{Pre}(s_3) \cap s_2 = [-0.5, 1.75] \cap [-1, 1] = [0.5, 1]$, and then $\text{PPre}^1(s_3, s_2) = \text{PPre}(\text{PPre}^0(s_3, s_2)) \cap s_2 = [-1.25, 1.875] \cap [-1, 1] = [-1, 1]$ is $s_2$. Further iterations produce no change, so $s_2$ does not need to be split because of $s_3$. In fact, no regions are split at all, and the initial partition is already a divergent stutter bisimulation. Differently, partitioning based on bisimulation splits $s_2$ into $\text{Pre}(s_3) \cap s_2 = [0.5, 1)$ and $[-1, 0.5)$, which require further splitting. Wagenmaker and Ozay (2016) show that there exists no finite bisimulation partition for this example. □

Like bisimulation, Algorithm 1 may fail to terminate when given an infinite state space. Yet there are cases such as the above example, where bisimulation fails to terminate while divergent stutter bisimulation yields a finite abstraction. It is clear and well-known that every bisimulation relation also is a divergent stutter bisimulation. It follows that Algorithm 1 terminates more often than bisimulation and always produces the same or a coarser abstraction.

4. Control strategy

This section presents the main contributions of the paper and shows how divergent stutter bisimulation can be used for synthesis. After partitioning the state space using Algorithm 1, the synthesis problem can be solved for the abstract system. It remains to construct a controller that solves Problem 1 for the original system. Next, Section 4.1 describes the construction of this controller, and afterwards Sections 4.2 and 4.3 show that the method is sound and complete.

4.1. Controller construction

Given a transition system $\mathcal{G}$ and LTL$_\varphi$ specification $\varphi$, the objective of this paper is to find a solution for Problem 1, i.e., a deadlock-free controller that enforces $\varphi$ on $\mathcal{G}$. Using Algorithm 1, the transition system is replaced by a divergent stutter bisimilar abstraction $\tilde{\mathcal{G}}$. Then a traditional synthesis procedure (Kloetzer & Belta, 2008; Ramadge, 1989) can be used to solve Problem 1 for the abstraction $\tilde{\mathcal{G}}$, which results in a controller $\tilde{C}$ that enforces the specification $\varphi$ on the abstraction $\tilde{\mathcal{G}}$.

It follows from the results cited in Section 3.2 that the system $\mathcal{G}$ and its abstraction $\tilde{\mathcal{G}}$ satisfy the same LTL$_\varphi$ properties, but this is only useful to verify that $\varphi$ holds on the uncontrolled system. After synthesis, it remains to be shown that the existence of the controller for the abstract system implies the existence of a controller for the original system. Therefore, it is now shown how the abstract controller $\tilde{C}$ that enforces the specification on the abstract system $\tilde{\mathcal{G}}$ can be used to design a controller $C$ that enforces the same specification on the original system $\mathcal{G}$. Its construction, which is given in Definition 16, works by considering the states in the original system $\mathcal{G}$ that correspond to the classes that form the abstraction $\tilde{\mathcal{G}}$.

The controller $C$ to be constructed for the original system observes a path $s = x_1 \cdots x_k$ and makes a control decision $C(s)$ of states allowed next. To base this decision on the abstract controller $\tilde{C}$, the path $s$ is mapped to a path $\tilde{s}$ of the abstract system, and then the control decision $\tilde{C}(\tilde{s})$ is used to inform the choice of $C(s)$.

Consider a path $\tilde{s} = \tilde{x}_1 \cdots \tilde{x}_k \in (Q/\approx)^+$ of the abstraction, which also is a state of the abstract controlled system $\hat{C}/\tilde{\mathcal{G}}$ by Definition 5. To use $\tilde{C}(\tilde{s})$ when making the control decision $C(s)$, it will be considered what classes can be reached from $\tilde{s}$ under control of $\tilde{C}$ after possible stuttering steps within $\tilde{x}_i$:

\[
\tilde{S}(\tilde{s}) = \{ \tilde{y} \in (Q/\approx) \mid \exists \tilde{x}_i \tilde{y} \text{ is a path in } \hat{C}/\tilde{\mathcal{G}} \} ;
\]

\[
\tilde{S}(\tilde{s}) = \bigcup_{i \geq 0} \tilde{S}(\tilde{s}) ;
\]

\[
\tilde{S}(\tilde{s}) \text{ is the set of equivalence classes that can be reached in the abstract controlled system after executing } \tilde{s} \text{ and then staying } i \text{ times in the last class } \tilde{x}_k \text{ of } \tilde{s}, \text{ and } \tilde{S}(\tilde{s}) \text{ is the set of equivalence classes reached after an arbitrary number of repetitions of the last class.}
\]

This allows for abstract controllers that transition from $\tilde{x}_k$ to the next class immediately, or that keep the system in $\tilde{x}_k$ for some number of steps before transitioning.

Now consider a finite path $s \in Q^+$ in $\mathcal{G}$, for which a control decision is to be made. This path is converted to a path $\tilde{s} \in (Q/\approx)^+$ so that $\tilde{C}(\tilde{s})$ can be used to inform the control decision $C(s)$. The path $\tilde{s}$ must be constructed in such a way that $\tilde{s}$ is a path in $\hat{C}/\tilde{\mathcal{G}}$ and is stutter equivalent to $s$. This is achieved by repeating each of the equivalence classes in $[s]$ for the smallest number of times needed to form a path in $\hat{C}/\tilde{\mathcal{G}}$. Specifically, $\tilde{s} = [s]_{\tilde{\mathcal{G}}}$ according to the following recursive definition, where $r \in Q^*$ and $x, y \in Q$:

\[
[y]_{\tilde{\mathcal{G}}} = \{y\} ; \tag{10}
\]

\[
[rxy]_{\tilde{\mathcal{G}}} = [rx]_{\tilde{\mathcal{G}}} , \quad \text{if } x \approx y ; \tag{11}
\]

\[
[rxy]_{\tilde{\mathcal{G}}} = [rx]_{\tilde{\mathcal{G}}} x[y]_{\tilde{\mathcal{G}}} , \quad \text{if } [y] \in \tilde{S}([rx]_{\tilde{\mathcal{G}}}) ; \tag{12}
\]

where $i = \min \{ i \geq 0 \mid [y] \in \tilde{S}([rx]_{\tilde{\mathcal{G}}}) \}$ in the last case. Also, $[s]_{\tilde{\mathcal{G}}}$ is undefined if none of the above conditions applies. By construction, $[s]_{\tilde{\mathcal{G}}}$ is stutter equivalent to $s$ if it is defined, and it is prefix-preserving, i.e., $s \subseteq t$ implies $[s]_{\tilde{\mathcal{G}}} \subseteq [t]_{\tilde{\mathcal{G}}}$ if defined.

Now the set of successors outside of the current class that $C$ allows after $s$ is the union of the classes that can be reached under control of $\tilde{C}$ after $[s]_{\tilde{\mathcal{G}}}$.

\[
S(s) = \bigcup \tilde{S}([s]_{\tilde{\mathcal{G}}}) . \tag{13}
\]

After observing $s \in Q^+$, the controller $C$ guides the system to a state in $S(s)$, possibly after stuttering steps within the class of the final state of $s$. If $\tilde{C}$ permits divergence, then $C$ allows it also,
otherwise it follows a shortest path to a state in $S(s)$. These ideas are formalised in the following definition.

**Definition 16.** Let $G = (Q, Q^*, \to, \Pi, \Rightarrow)$ be a transition system, let $\approx$ be an equivalence relation on $Q$, let $G = G/\approx$, and let $\tilde{C}$ be a controller for $G$. The controller $C : Q^* \to 2^Q$ for $G$ is constructed as follows. First, for the empty path $s = \epsilon$, we have $C(\epsilon) = \bigcup \tilde{C}(s)$. For a nonempty path $s = s_0 \cdots s_n \in Q^+$, the value of $C(s)$ depends on divergences:  

(i) If $[x_n]$ is not $\approx$-divergent in $G$ or $[s]_{\tilde{C}}$ is divergent in $\tilde{C}$, then

$$
C(s) = \{[x_n] \cup S(s) \}.
$$

(ii) If $[x_n]$ is $\approx$-divergent in $G$ and $[s]_{\tilde{C}}$ is not divergent in $\tilde{C}$, then

$$
C(s) = \begin{cases} 
S(s) & \text{if } i = 0; \\
\text{PPre}^{-1}(S(s), [x_n]) & \text{otherwise;}
\end{cases}
$$

where $i = \min\{j \geq 0 \mid x_n \in \text{PPre}(S(s), [x_n])\}$.

In Definition 16, $C$ allows as initial states all states in classes allowed as initial by $\tilde{C}$. Otherwise the decision depends on the equivalence class $[x_n]$ that corresponds to the last state of $s$.

In case (i), this class $[x_n]$ is not divergent or is divergent in the abstract controlled system, i.e., $[s]_{\tilde{C}}$ is last in $\tilde{C}/G$, and $C$ allows the system to stay in $[x_n]$ or to transit to the classes $S(s)$ allowed as successors by $\tilde{C}$. Fig. 1 shows the case of a non-divergent class to the left, and in the middle class that is divergent in the abstract controlled system.

In case (ii), $[x_n]$ is a divergent class in the uncontrollable system but the abstract controller $\tilde{C}$ does not allow this divergence. The controller $C$ prevents the divergent behaviour within $[x_n]$ and forces the system to transition to a different equivalence class eventually. The construction (15) ensures that the system transitions to another equivalence class permitted by the abstract controller when possible, and otherwise only allows transitions within $[x_n]$ that take the system closer to a state from where it is possible to leave $[x_n]$. This case is shown in Fig. 1 to the right.

### 4.2. Soundness

**Soundness** means that any controller synthesised by the abstraction-based method correctly solves Problem 1. Here it is shown that if there exists a solution $\tilde{C}$ to the synthesis problem for an abstracted system $\tilde{G}$, then the controller constructed according to Definition 16 solves the synthesis problem for the original system $G$.

For the controller to be correct, it must enforce its LTL* specification and be deadlock free, which is shown in Propositions 4 and 5. Both results depend on the following lemma, which shows that the path $[s]_{\tilde{C}}$ used in the construction of the controller $C$ is a path in the abstract controlled system $\tilde{C}/G$ if $s$ is a path in the original controlled system $G$.

**Lemma 3.** Let $G$ be a transition system, let $\approx$ be a divergence stutter bisimulation on $G$, let $\psi$ be a controller for $G = G/\approx$, and let $C$ be the controller constructed from $\psi$ according to Definition 16. If a finite string $s \in Q^*$ is a path in $C/\tilde{G}$, then $[s]_{\tilde{C}}$ is defined and is a path in $\tilde{C}/G$.

**Proof.** Let $s = s_0 \cdots s_n$ and let $s_k = s_0 \cdots s_k$ be the $k$th prefix of $s$. It is shown by induction on $k = 0, \ldots, n$ that $[s_k]_{\tilde{C}}$ is defined and a path in $\tilde{C}/G$.

Base case: $k = 0$. As $s_0 = x_0$ is a path in $C/G$, it is clear that $x_0 \in Q^*$ is an initial state of $G$ and $x_0 \in C(\epsilon)$. Then $[x_0] \in \{[x^*] \mid x^* \in Q^*\} = \tilde{Q}^*$ is an initial state of $\tilde{G}$, and from $x_0 \in C(\epsilon) = \bigcup \tilde{C}(\epsilon)$ it follows that $[x_0] \in C(\epsilon)$. This means that $[x_0]$ is an initial state of $C/\tilde{G}$, which implies that $[s_0]_{\tilde{C}} = [x_0]$ is defined and a path in $C/\tilde{G}$.

Inductive step: Assume the claim holds for some $0 \leq k < n$, i.e., $[s_k]_{\tilde{C}}$ is defined and a path in $C/\tilde{G}$. It must be shown that $[s_{k+1}]_{\tilde{C}}$ is defined and a path in $C/\tilde{G}$. As $k \geq 0$, the path $s_kx_{k+1}$ can be written as $s_kx_{k+1} = s_kx_{k-1}x_{k+1}$. As $s$ and thus its prefix $s_{k+1}$ is a path in $C/\ tilde{G}$, it is clear that $x_{k+1} \in C(s_k)$ by Definition 6. Consider two cases.

If $\tilde{s}_k \approx x_{k+1}$, then it follows by (11) that $[s_{k+1}]_{\tilde{C}} = [s_kx_{k+1}]_{\tilde{C}} = [s_kx_{k-1}]_{\tilde{C}} = [s_k]_{\tilde{C}}$ is defined and a path in $C/\tilde{G}$ by the inductive assumption.

Otherwise $x_{k+1} \notin C(s_k)$ it follows in both cases (i) and (ii) of Definition 16 that $s_{k+1} \in S(s_k)$. (For case (ii), note that $\text{PPre}^{-1}(S(s_k), [x_n]) \subseteq [x_n]$.) Choose $x \in \tilde{S}(s_{k+1})$ such that $x_{k+1} \approx x$, i.e., $x_{k+1} \notin x$. Then by (8)-(9), there exists $x \geq 0$ such that $[s_k]_{\tilde{C}}[x^*]x = [s_k]_{\tilde{C}}[x^*]x_{k+1}$ is a path in $C/\tilde{G}$. Choose $i$ to be the smallest with this property. Then $[s_k]_{\tilde{C}}[x^*]x_{k+1} = [s_k]_{\tilde{C}}[x^*]x_{k+1}$ is a path in $C/\tilde{G}$ by (10). Hence $[s_k]_{\tilde{C}}$ is defined and a path in $C/\tilde{G}$. □

Now it can be shown that the controller constructed according to Definition 16 enforces the same LTL* properties on the original system as the abstract controller does.

**Proposition 4.** Let $G$ be a transition system, let $\approx$ be a divergent stutter bisimulation on $G$, let $\psi$ be an LTL* specification, let $C$ be a controller for $G = G/\approx$ that enforces $\psi$ on $G$, and let $C$ be the controller constructed from $\psi$ according to Definition 16. Then $C$ enforces $\psi$ on $G$.

**Proof.** Assume $s = x_0x_1 \cdots x_n$ is an arbitrary infinite path in $C/G$. It is to be shown that $s \models \psi$. By Lemma 3, for every prefix $s_n = x_0 \cdots x_n$ of $s$, it holds that $[s_n]_{\tilde{C}}$ is defined and is a path in $C/\tilde{G}$. Therefore, as $[s]_{\tilde{C}}$ is prefix-preserving, there is an ascending sequence $[s_0]_{\tilde{C}} \subseteq [s_1]_{\tilde{C}} \subseteq \cdots$ of paths in $C/G$. The closure of this sequence may be finite or infinite.

If it is finite, then let $\tilde{s} = \text{clo}([s_n]_{\tilde{C}} \mid i \geq 0)$, which is an infinite path in $C/\tilde{G}$ and stutter equivalent to $s$.

Otherwise there exists $k \geq 0$ such that $[s_k]_{\tilde{C}} = [s_n]_{\tilde{C}}$ for all $n \geq k$. As $[s_n]_{\tilde{C}}$ is defined for all $n \geq 0$, it must have been constructed from (11) and $x_0 \approx x_k$ for all $n \geq k$. As $s$ is a path in $G$, it follows that $s_k$ is divergent in $C/G$ and $x_k$ is divergent in $C$. The fact that $s_k$ is divergent in $C/G$ means that $C(s_k)$ cannot be constructed according to case (ii) of Definition 16, as this case only allows a finite number of steps within $[x_n]$. Then case (i) of Definition 16 must be used, i.e., $[s_k]_{\tilde{C}}$ is divergent in $C/G$. This means by Definition 7 that $\tilde{s} = [s_k]_{\tilde{C}}[x_n][x_n] \cdots$ is an infinite path in $C/\tilde{G}$. Also, as $[x_n] = [x_n]$ for all $n \geq k$, it is clear that $\tilde{s}$ is stutter equivalent to $s$.

In both cases, there exists an infinite path $\tilde{s}$ in $C/\tilde{G}$ that is stutter equivalent to $s$. Since $C$ enforces $\psi$ on $G$, it follows that $\tilde{s} \models \psi$. Since $\tilde{s}$ is stutter equivalent to $s$, based on Proposition 1 it holds that $s \models \psi$. □

The second property required of a correct controller is that it is deadlock free. Therefore, the following proposition establishes that if the abstracted closed-loop system is deadlock free, then the controller constructed using Definition 16 produces a deadlock free closed-loop behaviour for the original system.

**Proposition 5.** Let $G$ be a transition system, let $\approx$ be a divergent stutter bisimulation on $G$, let $C$ be a controller for $G = G/\approx$ such that $C/\tilde{G}$ is deadlock free, and let $C$ be the controller constructed from $\tilde{C}$ according to Definition 16. Then $C/G$ is deadlock free.
Proof. Consider a reachable state $s$ of $C/G$, which can be written as $s = x_0 \cdots x_n$, which must be a path in $C/G$. It follows by Lemma 3 that $[s]_{\bar{C}}$ is defined and is a path in $\bar{C}/G$. By construction, $[s]_{\bar{C}}$ can be written as $[s]_{\bar{C}} = x_0 \cdots x_n$ with $x_0 \in \bar{x}_0$.

First consider the case that $[s]_{\bar{C}}$ is divergent in $\bar{C}/G$, which by Definition 7 means that $\bar{x}_0 \bar{x}_1 \cdots \bar{x}_k \bar{x}_k \cdots$ is a path in $\bar{C}/G$. This implies that $\bar{x}_k$ is divergent in $G$, and as $\bar{C}/G$ is a divergence stutter bisimulation on $G$, it follows that $[x_k]_G = \bar{x}_k$ is $\approx$-divergent in $G$. Then there exists $x_{k+1} \in [x_k]$ such that $x_k \rightarrow x_{k+1}$ in $G$. Also $C(s)$ is constructed according to case (i) of Definition 16 for divergent $[s]_{\bar{C}}$, and thus $x_{k+1} \in [x_k] \subseteq [x_k] \cap S(s) = [s]_S$.

Now consider the case that $[s]_{\bar{C}}$ is not divergent in $\bar{C}/G$. Then, since $\bar{C}/G$ is deadlock free, there must exist $i \geq 0$ and a class $\bar{y} \neq \bar{x}_k$ such that $[s]_{\bar{C}} \bar{y}$ is a path in $\bar{C}/G$. It follows from (8)–(9) that $\bar{y} \in [s]_{\bar{C}}$. Also, as $[s]_{\bar{C}} \bar{y}$ is a path in $\bar{C}/G$, it holds that $\bar{x}_k \rightarrow \bar{y}$ in $G$, which means that there exists states $x \in \bar{x}_k$ and $y \in \bar{y}$ such that $x \rightarrow y$ in $G$. Then $x_n \approx x$, and as $\approx$ is a divergence stutter bisimulation on $G$, there exists a path fragment $x_0 \rightarrow x_{n+1} \rightarrow \cdots \rightarrow x_{n+m} \approx y$ (16) in $G$ where $x_n, \ldots, x_{n+m-1} \in \bar{x}_k$ and $x_{n+m} \in \bar{y}$. Assume without loss of generality that (16) is a shortest path fragment with these properties. Note that, as $x_{n+m} \in \bar{y}$ and $y \in \bar{s}(s)$, it follows from (13) that $x_{n+m} \in S(s)$. Now consider the two cases from Definition 16.

(i) $[x_k]_G$ is not divergent and $C(s) = [x_k] \cup S(s)$. Either it holds that $m > 1$ and $x_{n+1} \in [x_k]$ or $m = 1$ and $x_{n+1} \in [x_k] \cap S(s)$, so it follows that $x_{n+1} \in [x_k] \cup S(s) = C(s)$.

(ii) $[x_k]_G$ is divergent and $C(s)$ is defined by (15). It is first shown by induction on $j = 0, \ldots, m-1$ that $x_{n+m-j-1} \in PPre(S(s)) \cap [x_k] = PPre^0(S(s), [x_k])$.

Base case: $j = 0$. As $x_{n+m-1} \in [x_k]$ and $x_{n+m-1} \rightarrow x_{n+m} \in S(s)$, it holds that $x_{n+m-1} \in PPre(S(s)) \cap [x_k] = PPre^0(S(s), [x_k])$.

Inductive step: Assume the claim $x_{n+m-j-1} \in PPre^0(S(s), [x_k])$ holds for some $j < m - 1$. Then since $x_{n+m-j-1} = x_{n+m-j-2} \rightarrow x_{n+m-j-1}$ in $G$ and $x_{n+m-j-1} \in \bar{x}_k = [x_k]$, it is clear that $x_{n+m-j-1} \in PPre(S(s), [x_k]) \subseteq PPre^0(S(s), [x_k]) = PPre^{m-1}(S(s), [x_k])$. This completes the induction. If $m = 1$ then it follows with $j = 0$ that $x_0 \in PPre^0(S(s), [x_k])$, and thus $x_{n+1} = x_{n+m} \in S(s) = C(s)$ from (15). If $m > 1$ then it follows with $j = m - 2$ that $x_{n+1} = PPre^{m-2}(S(s), [x_k])$. Also, since (16) is a shortest path fragment, there does not exist $j < m - 2$ such that $x_{n+1} \in PPre^{m-2}(S(s), [x_k])$. Then it follows from (15) that $x_{n+1} \in PPre^{m-2}(S(s), [x_k]) = C(s)$.

In all the cases there exists $x_{n+1} \in C(s)$ with $x_n \rightarrow x_{n+1}$. It follows that $s \rightarrow x_{n+1}$ in $C/G$, which shows that $C/G$ is deadlock free. \(\square\)

The following theorem combines the results from Propositions 4 and 5 to show that synthesis after divergence stutter bisimulation is sound.

**Theorem 6 (Soundness).** Let $G$ be a transition system and $\varphi$ be an LTL$_{\text{o}}$ formula. Let $\bar{C}$ be a controller for $G = G/\approx$ such that $C/G$ is deadlock free and $C/G \models \varphi$. Let $C$ be the controller constructed from $\bar{C}$ according to Definition 16. Then $C/G$ is deadlock free and $C/G \models \varphi$. \(\square\)

**Proof.** Follows directly from Propositions 4 and 5. \(\square\)

Theorem 6 establishes that divergence stutter bisimulation can be used as an abstraction method before solving Problem 1. Moreover, Definition 16 can be used to construct a controller for the original system from the abstracted controller, which is a solution for Problem 1.

4.3. Completeness

Completeness of a synthesis method means that if there exists a solution to the synthesis problem, then the method finds a solution. The following theorem shows that, if there exists a controller $C$ for a system $G$, then there also exists a controller $\bar{C}$ that enforces the same LTL$_{\text{o}}$ specification on the divergence stutter bisimilar abstraction $\bar{G}$.

**Theorem 7 (Completeness).** Let $G$ be a transition system, let $\approx$ be a divergence stutter bisimulation on $G$ and let $\varphi$ be an LTL$_{\text{o}}$ specification, and let $C$ be a controller for $G$ that enforces $\varphi$ on $G$ such that $C/G$ is deadlock free. Then there exists a controller $\bar{C}$ for $G = G/\approx$ that enforces $\varphi$ on $G$ such that $\bar{C}/G$ is deadlock free.

**Proof.** Since $C/G$ is deadlock free, from every initial state of $C/G$ there exists an infinite path in $C/G$. Let $Q^+_G = \{[x^+]: x^+ \in Q^+ \cap C(s)\}$ be the set of classes of initial states allowed by $C$. Then choose an initial class $\bar{x}_0 \in \bar{Q}^+_G$, and an initial state $x_0 \in \bar{x}_0 \cap Q^+ \cap C(s)$, and an infinite path $s = x_0 \bar{x}_1 \cdots \in C/G$. As $s$ is an infinite path in $G$, by Theorem 2, there exists a stutter equivalent infinite path $\bar{s} = \bar{x}_0 \bar{x}_1 \cdots \in G$. Now construct the controller $\bar{C}$ such that $\bar{C}(s) \models [x_0]_{\bar{C}}$ and $[x_0]_{\bar{C}} \cdots \bar{x}_k \cdots = [\bar{x}_k]$ for all $k \geq 0$. By construction, $\bar{C}$ constrains the abstracted system $\bar{G}$ such that it can only follow the infinite path $\bar{s}$, which implies that $\bar{G}/G$ is deadlock free. As $s$ is a path in $C/G$, and $C$ enforces $\varphi$ on $G$, it holds that $s \models \varphi$. As $s$ is stutter equivalent to $\bar{s}$, it follows by Proposition 1 that $\bar{s} \models \varphi$. Then, since $\bar{s}$ is the only infinite path in $\bar{C}/G$, it follows that $\bar{C}$ enforces $\varphi$ on $G$. \(\square\)

Theorem 7 confirms that, whenever there exists a solution to Problem 1, the method of synthesis after divergence stutter bisimulation also finds a solution. Assume that there exists a controller $C$ that enforces a given LTL$_{\text{o}}$ specification on a given system $G$. Then by Theorem 7, there exists controller $\bar{C}$ that enforces the same specification on the abstraction $\bar{G}$. Given a complete procedure to solve the synthesis problem for $G$, it is possible to compute such a solution. This solution can then be converted to a controller for the original system using Definition 16, which by the results of Section 4.2 solves Problem 1 for the original system.
Consider a system where

**Example 2.** A CPU with 32 GiB of RAM. All computations were performed on an Intel i7-4770K closed-loop systems are simulated using TuLiP (Filippidis et al., 2016). The systems are abstracted, controllers are synthesised, and the faster computation is demonstrated with the next two examples applicable, stutter bisimulation can offer simpler partitions and stutter bisimulation partition exists. Even when bisimulation is divergent stutter bisimulation to a variety of systems and compares the results to regular bisimulation.

As shown in **Example 1**, there are cases where the coarsest partition for bisimulation is infinite while a finite divergent stutter bisimulation partition exists. Even when bisimulation is applicable, stutter bisimulation can offer simpler partitions and faster computation. This is demonstrated with the next two examples featuring finite and continuous state spaces. In both cases the systems are abstracted, controllers are synthesised, and the closed-loop systems are simulated using TuLiP (Filippidis et al., 2016). All computations were performed on an Intel i7-4770K CPU with 32 GiB of RAM.

**Example 2.** Consider a system where $K$ robots, numbered 1, $\ldots$, $K$, navigate in a two-dimensional grid $G = \{0, \ldots, w\} \times \{0, \ldots, h\}$. The system state $x$ consists of the robot locations $x_1, \ldots, x_K \in G$ and evolves according to

$$x^{+} = x + u, \quad u \in \left[-\frac{1}{2}, \frac{1}{2}\right]^2.$$  

**Example 3.** Consider a continuous analogue of **Example 2** with one robot modelled by the linear system

$$x^{+} = x + u, \quad u \in \left[-\frac{1}{2}, \frac{1}{2}\right]^2.$$  

The state space $Q$ is a subset of $[0, 6] \times [0, 4]$ with polygonal obstacles as shown in Fig. 3 removed. The atomic propositions are as in **Example 2**, and the satisfaction relation is defined similarly where the home and task locations are squares at the corners of $Q$.

The abstraction algorithms are implemented for regions given by unions of polytopes whose predecessors can be computed with linear programming. The bisimulation algorithm is prematurely terminated by splitting only regions exceeding a minimum area, resulting in an abstraction with 158 regions that takes 349 s to compute. The divergent stutter bisimulation algorithm takes 2003 s and converges to the original partition. These abstractions are depicted in Fig. 3.

![Fig. 2. Abstraction sizes and computation times (top) and synthesis and simulation times (bottom) from **Example 2**.](image)

![Fig. 3. The abstractions in **Example 3** using bisimulation (left) and divergent stutter bisimulation (right). A path using the synthesised controller is shown for the divergent stutter bisimulation.](image)
Next, when synthesising controllers, the computer runs out of memory during synthesis for bisimulation, while a controller is synthesised in 38 ms for the much smaller divergent stutter bisimulation abstraction. When simulating a path of the closed-loop system for the divergent stutter bisimulation abstraction, the average time to map control inputs for the abstraction to the original system is 0.81 ms.

Even when divergent stutter bisimulation does not result in the original partition, the resulting abstraction can still be significantly less complex than abstractions using bisimulation, as shown in the next two examples.

**Example 4.** Consider the following continuous-state double-integrator system:

\[
\begin{bmatrix}
  x^+ \\
  v^+ 
\end{bmatrix} = \begin{bmatrix}
  1 & 1 \\
  0 & 1 
\end{bmatrix} \begin{bmatrix}
  x \\
  v 
\end{bmatrix} + \begin{bmatrix}
  0 \\
  1 
\end{bmatrix} u ,
\]

where \( x \in [-1, 1] \), \( v \in \mathbb{R} \), and \( u \in [-0.5, 0.5] \). This models the position \( x \) and velocity \( v \) of a ball rolling on a one-dimensional table that can be tilted. The objective is for the ball to visit two regions \( L = [-1, -0.5] \) and \( R = [0.5, 1] \) repeatedly, which is expressed in LTL \( \varphi \) as \( \Box \Diamond l \land \Box \Diamond r \), where \((x, v) \models l\) if \( x \leq -0.5 \) and \((x, v) \models r\) if \( x \geq 0.5 \). The bisimulation algorithm terminates in 48 s resulting in an abstraction with 82 regions, while the divergent stutter bisimulation algorithm converges in 200 s to an abstraction with 30 regions, as shown in Fig. 4. Although divergent stutter bisimulation takes longer to compute, it results in a smaller abstraction.

**Example 5** ([Wagenmaker & Ozay, 2016]). Consider the following two-dimensional linear system:

\[
\begin{bmatrix}
  x^+ \\
  v^+ 
\end{bmatrix} = \begin{bmatrix}
  0.5 & 1 \\
  0.75 & -1 
\end{bmatrix} \begin{bmatrix}
  x \\
  v 
\end{bmatrix} + u ,
\]

where \( x \in [-1, 1] \times [-1, 1] \) is the state and \( u \in [-1, 1] \times [-1, 1] \) is the control input. The initial partition consists of five regions, \( s_1 = [-0.5, 0.5] \times [-0.5, 0.5] \), \( s_2 = [-1, 0.5] \times [-1, 1] \), \( s_3 = [-0.5, 1] \times [0.5, 1] \), \( s_4 = [0.5, 1] \times [-1, 0.5] \), and \( s_5 = [-0.5, 0.5] \times [-1, -0.5] \). Divergent stutter bisimulation converges to a partition of 15 regions as shown in Fig. 5, after 37 s computation time. The dual-simulation algorithm converges to a partition of 66 regions after 137 s, while the bisimulation algorithm does not terminate after 1 h—it produces an approximate partition of 700 regions in 35 min. Wagenmaker and Ozay (2016). □

**6. Conclusions**

The abstraction method of *divergent stutter bisimulation* has been applied to reduce a state space before controller synthesis. Divergent stutter bisimulation is a well-known abstraction in the field of model checking, which preserves CTL \( \varphi \) properties. This paper leverages these results to simplify the task of controller synthesis. It is shown that a controller synthesised to satisfy any LTL \( \varphi \) specification on a reduced state space based on divergent stutter bisimulation can be converted back to a controller for the original system. This synthesis method is sound and complete relative to a sound and complete synthesis procedure for the abstract state space.

These results improve on bisimulation-based abstraction, because divergent stutter bisimulation results in coarser partitions and is more likely to terminate even for infinite state spaces. This abstraction can also be considered as more insightful for continuous systems as it ignores the number of steps needed to transition from one region to another.

In future work, the authors would like to combine divergent stutter bisimulation with dual-simulation ([Wagenmaker & Ozay, 2016]). Dual-simulation is related to simulation equivalence ([Henzinger et al., 2005]) and improves on bisimulation using covers instead of partitions, and could benefit from the abstraction of stuttering steps in the same way as bisimulation does. It would also be interesting to generalise the results about LTL \( \varphi \) specifications to CTL \( \varphi \), or CTL \( \varphi \), and to consider control under uncertainty or disturbance.

Sahar Mohajerani received her M.S. degree in Systems, Control, and Mechatronics from and her Ph.D. in Automation from Chalmers University of Technology, in 2009 and 2015, respectively. She worked at Volvo Cars Corporation on function verification for two years, until 2017. She was a post-doctoral fellow at the University of Michigan from 2017 to 2019, where she worked on security and privacy verification of cyber-physical systems. She received the Best Student Paper Award at IFAC-IEEE International Workshop on Discrete Event Systems in 2014 (for a paper co-authored with R. Malik and M. Fabian). She is currently an assistant professor in the Department of Electrical Engineering at Chalmers University of Technology. Her research interests include formal methods for verification and synthesis of large discrete event systems and cyber-physical systems.

Robi Malik received the M.S. and Ph.D. degree in computer science from the University of Kaiserslautern, Germany, in 1993 and 1997, respectively. From 1998 to 2002, he worked in a research and development group at Siemens Corporate Research in Munich, Germany, where he was involved in the development and application of modelling and analysis software for discrete event systems. Since 2003, he is lecturing Computer Science at the University of Waikato in Hamilton, New Zealand. He is participating in the development of the Supremeca software for modelling and analysis of discrete event systems. His current research interests are in the area of model checking and synthesis of large discrete event systems and other finite-state machine models.

Andrew Wintenberg received his B.S. degree in Electrical Engineering and Mathematics from The University of Tennessee, Knoxville, USA, in 2018 and his M.S. degree in Electrical Engineering from the University of Michigan, Ann Arbor, in 2020, where he is currently a Ph.D. candidate. His research interests include the safety and security of discrete-event and cyber-physical systems through formal methods and abstraction.

Stéphane Lafortune received the B.Eng degree from Ecole Polytechnique de Montréal in 1980, the M.Eng degree from McGill University in 1982, and the Ph.D degree from the University of California at Berkeley in 1986, all in electrical engineering. Since September 1986, he has been with the University of Michigan, Ann Arbor, where he is a Professor of Electrical Engineering and Computer Science. In March 2018, he was appointed as the N. Harris McClamroch Collegiate Professor of Electrical Engineering and Computer Science. Lafortune is a Fellow of the IEEE (1999) and of IFAC (2017). He received the Presidential Young Investigator Award from the National Science Foundation in 1990 and the Axelby Outstanding Paper Award from the Control Systems Society of the IEEE in 1994 (for a paper co-authored with S.-L. Chung and F. Lin) and in 2001 (for a paper co-authored with G. Barrett). Lafortune’s research interests are in discrete event systems and include multiple problem domains: modelling, diagnosis, control, optimisation, and applications to computer and software systems. He served as Editor-in-Chief of the Journal of Discrete Event Dynamic Systems: Theory and Applications from 1/2015 to 12/2020.

Necmiye Ozay received the B.S. degree from Bogazici University, Istanbul in 2004, the M.S. degree from the Pennsylvania State University, University Park in 2006 and the Ph.D. degree from Northeastern University, Boston in 2010, all in electrical engineering. She was a postdoctoral scholar at California Institute of Technology, Pasadena between 2010 and 2013. She is currently an associate professor of Electrical Engineering and Computer Science, at University of Michigan, Ann Arbor. Her research interests include control of dynamical systems, optimisation, and formal methods with applications in cyber-physical systems, system identification, verification & validation, and autonomy.
