ABSTRACT

In anticipation of improved observational data for Jupiter’s gravitational field, from the Juno spacecraft, we predict the static tidal response for a variety of Jupiter interior models based on ab initio computer simulations of hydrogen–helium mixtures. We calculate hydrostatic-equilibrium gravity terms, using the non-perturbative concentric Maclaurin Spheroid method that eliminates lengthy expansions used in the theory of figures. Our method captures terms arising from the coupled tidal and rotational perturbations, which we find to be important for a rapidly rotating planet like Jupiter. Our predicted static tidal Love number, \(k_2\), is \(0.5900\), is \(\sim 10\% \) larger than previous estimates. The value is, as expected, highly correlated with the zonal harmonic coefficient \(J_2\), and is thus nearly constant when plausible changes are made to the interior structure while holding \(J_2\) fixed at the observed value. We note that the predicted static \(k_2\) might change, due to Jupiter’s dynamical response to the Galilean moons, and find reasons to argue that the change may be detectable—although we do not present here a theory of dynamical tides for highly oblate Jovian planets. An accurate model of Jupiter’s tidal response will be essential for interpreting Juno observations and identifying tidal signals from effects of other interior dynamics of Jupiter’s gravitational field.

Key words: planets and satellites: fundamental parameters — planets and satellites: gaseous planets — planets and satellites: individual (Jupiter) — planets and satellites: interiors

1 INTRODUCTION

The Juno spacecraft began studying Jupiter at close range following its orbital insertion in early 2016 July. The unique low-periapse polar orbit and precise Doppler measurements of the spacecraft’s acceleration will yield parameters of Jupiter’s external gravitational field with unprecedented precision, approaching a relative precision of \(\sim 10^{-9}\) (Kaspi et al. 2010). In addition to providing important information about the planet’s interior mass distribution, the non-spherical components of Jupiter’s gravitational field should exhibit a detectable signal from tides induced by the planet’s closer large moons, possibly superimposed on signals from mass anomalies induced by large-scale dynamic flows in the planet’s interior (Kaspi et al. 2010; Kaspi 2013; Cao & Stevenson 2015).

As a benchmark for comparison with expected Juno data, Hubbard & Militzer (2016) constructed static interior models of the present state of Jupiter, using a barotropic pressure–density \(P(\rho)\) equation of state for a near-solar mixture of hydrogen and helium, determined from ab initio molecular dynamics simulations (Militzer 2013; Militzer & Hubbard 2013). In this paper, we extend those models to predict the static tidal response of Jupiter, using the three-dimensional concentric Maclaurin spheroid (CMS) method (Wahl et al. 2016).

The Hubbard & Militzer (2016) preliminary Jupiter model is an axisymmetric, rotating model with a self-consistent gravitational field, shape, and interior density profile. It is constructed to fit pre-Juno data for the degree-two zonal gravitational harmonic \(J_2\) (Jacobson 2003). Solutions exist matching pre-Juno data for the degree-four harmonic \(J_4\); however, models that use the ab initio EOS require unphysical compositions with densities lower than that expected for the pure H–He mixture. As a result, the preferred model of Hubbard & Militzer (2016) predicts a \(J_4\) with an absolute value above pre-Juno error bars. Preliminary Jupiter models consider the effect of a helium rain layer where hydrogen and helium become immiscible ( Stevenson & Salpeter 1977b). The existence of such a layer has important effects for the interior structure of the planet, because it inhibits convection and mixing between the molecular exterior and metallic interior portions of the H–He envelope. This circumstance provides a physical basis for differences in composition and thermal state between the inner and outer portions of the planet. Adjustments of the heavy element content and entropy of the \(P(\rho)\) barotrope allow identification of an interior structure consistent with both pre-Juno observational constraints and the ab initio material simulations. The preferred preliminary model predicts a dense inner core with \(\sim 12\) Earth masses and an inner hydrogen–helium rich envelope with \(\sim 3\times\) solar metallicity, using an outer envelope composition matching that measured by the Galileo entry probe.

Although the Cassini Saturn orbiter was not designed for direct measurements of the high-degree and -order components of Saturn’s gravitational field, the first observational determination of Saturn’s second-degree Love number \(k_2\) was recently reported by Lainey et al. (2016). This study used an astrometric data set for Saturn’s co-orbital satellites to fit \(k_2\), and identified a value significantly larger than the theoretical prediction of Gavrilov & Zharkov (1977). The non-perturbative CMS method obtains values of \(k_2\) within the observational error bars for simple models of Saturn’s interior, indicating the high value can be explained completely in terms of static tidal response (Wahl et al. 2016). The perturbative method of Gavrilov & Zharkov (1977) provides an initial estimate of tidally induced terms in the gravitational potential, but neglects terms on the order of the product of tidal and rotational perturbations. Wahl et al. (2016) demonstrated that, for the rapidly rotating Saturn, these terms are significant and sufficient to explain the observed enhancement of \(k_2\).
2. BAROTROPE

We assume the liquid planet is in hydrostatic equilibrium,
\[ \nabla P = \rho \nabla U, \]
where \( P \) is the pressure, \( \rho \) is the mass density, and \( U \) is the total effective potential. Modeling the gravitational field of such a body requires a barotrope \( P(\rho) \) for the body’s interior. In this paper, we use the barotrope of Hubbard & Militzer (2016), constructed from ab initio simulations of hydrogen–helium mixtures (Militzer 2013; Militzer & Hubbard 2013). The \( P(\rho) \) relation is interpolated from a grid of adiabats determined from density functional molecular dynamics (DFT-MD) simulations, using the Perdew–Burke–Ernzerhof functional (Perdew et al. 1996) in combination with a thermodynamic integration technique. The simulations were performed with cells containing \( N_{\text{He}} = 18 \) helium and \( N_{\text{H}} = 220 \) hydrogen atoms, corresponding to a solar-like helium mass fraction \( Y_0 = 0.245 \). An adiabat is characterized by an entropy per electron \( S/k_B/N_e \) (Militzer & Hubbard 2013), where \( k_B \) is Boltzmann’s constant and \( N_e \) is the number of electrons. Hereafter, we refer to this quantity simply as \( S \).

In our treatment, the term “entropy” and the symbol \( S \) refer to a particular adiabatic temperature \( T(P) \) relationship for a fixed-composition H–He mixture \( (Y_0 = 0.245) \), as determined from the ab initio simulations. The value of \( S \) in the outer portion of the planet is determined by matching the \( T(P) \) measurements from the Galileo atmospheric probe (see Figure 1). This adiabatic \( T(P) \) is assumed to apply to small perturbations of composition, in terms of both helium fraction and metallicity. Hubbard & Militzer (2016) demonstrated that these compositional perturbations have a negligible effect on temperature distribution in the interior.

The density perturbations for the equation of state are estimated using the additive volume law,
\[ V(P, T) = V_{\text{H}}(P, T) + V_{\text{He}}(P, T) + V_Z(P, T), \]
where the total volume \( V \) is the sum of the partial volumes of main components \( V_{\text{H}} \) and \( V_{\text{He}} \), and the heavy element component \( V_Z \). Hubbard & Militzer (2016) demonstrated that this leads to a modified density \( \rho \) in terms of the original H–He EOS density \( \rho_0 \).
\[ \rho_0 = \frac{1 - Y - Z}{1 - Y_0} + \frac{Z Y_0 + Y - Y_0}{1 - Y_0} \frac{\rho_0}{\rho_{\text{He}}} + \frac{Z}{\rho_Z}, \]
in which all densities are evaluated at the same \( T(P) \), and \( Y_0 \) is the helium fraction used to calculate the H–He equation of state.

The choice of equation of state affects the density structure of the planet, and consequently, the distribution of heavy elements that is consistent with observational constraints. For comparison, we also construct models using the Saumon et al. (1995) equation of state (SCvH) for H–He mixtures, which has been used extensively in giant planet modeling.

Ab initio simulations show that, at the temperatures relevant to Jupiter’s interior, there is no distinct, first-order phase transition between molecular (diatomic, insulating) hydrogen to metallic (monatomic, conducting) hydrogen (Vorburger et al. 2007). In the context of a planet-wide model, however, the transition takes place over the relatively narrow pressure range between \( 1–2 \) Mbar. Within a similar pressure range, an immiscible region opens in the H–He phase diagram Morales et al. (2013), which—under correct conditions—allows for a helium rain layer Stevenson & Salpeter (1977a, 1977b). By comparing our adiabat calculations to the Morales et al. (2013) phase diagram, we predict such a helium rain layer in present-day Jupiter (Hubbard & Militzer 2016). The extent of this layer in our models is highlighted in Figure 1. Although the detailed physics involved with the formation and growth of a helium rain layer are poorly understood, the existence of a helium rain layer has a number of important consequences for the large-scale structure of the planet. In our models, we assume this process introduces a superadiabatic temperature gradient and a compositional difference between the outer, molecular layer and inner, metallic layer.

In summary, the barotrope and resulting suite of axisymmetric Jupiter models that we use in this investigation are identical to the results presented by Hubbard & Militzer (2016). Each model has a central core mass and envelope metallicities set to fit the observed \( J_2 \) (Jacobson 2003), with densities...
corrected to be consistent with the non-spherical shape of the rotating planet. Because tidal corrections to a rotating Jupiter model are of order 10−7 (see Table 1 and the following section), it is unnecessary to re-fit the tidally perturbed models to the barotrope assumed for axisymmetric models.

The physical parameters for each of these models are summarized in Table 2. The gravitational moments at the planet’s surface are insensitive to the precise distribution of extra heavy-element rich material within the innermost part of the planet. For instance, the gravitational moments do not allow us to discern between a model with a dense rocky core and a model without one, but with same amount of heavy elements distributed in a larger (but restricted) volume within the deep interior. Maintaining a constant core radius is computationally convenient when finding a converged core mass for J2, because it requires no modification of the radial grid used through the envelope. For this reason, we consider models with a constant core radius of 0.15a. Decreasing this radius below 0.15a for a given core mass has a negligible effect on the calculated gravitational moments (Hubbard & Militzer 2016). Figure 2 shows the density profile for two representative models. In general, models using the DFT-MD equation of state lead to a larger central core and a lower envelope metallicity than those using SCvH. Hubbard & Militzer (2016) also noted that these models predict a value for J4 outside the reported observational error bars (Jacobson 2003), because they would require unrealistic negative values for Z to match both J2 and J4.

### 3. STATIC TIDE CALCULATIONS

To calculate the gravitational moments, we use the non-perturbative CMS method that was introduced by Hubbard (2012, 2013) and extended to three dimensions by Wahl et al. (2016). In this method, the density structure is parameterized by N nested constant-density spheroids. For a given set of spheroids, the gravitational field is calculated as a volume-integrated function of all of the spheroids. The method then iterates to find the shape of each spheroid, such that the surface of each is an equipotential surface under the combined effect of the planet’s self-gravity, the centrifugal potential from rotation, and the external gravitational perturbation from a satellite. The result is a model with self-consistent shape, internal density distribution, and gravitational field described up to a chosen harmonic degree and order limit, nlim.

The non-spherical components of the gravitational potential are described by two non-dimensional numbers

\[ q_{\text{rot}} = \frac{\omega^2 a^3}{GM}, \]  

(4)

describing the relative strength of the rotational perturbation, and

\[ q_{\text{tid}} = -\frac{3m_{\text{sat}} a^3}{MR^3}, \]  

(5)

the analogous quantity for the tidal perturbation. Here, G is the universal gravitational constant, M is the total mass of the planet, a is the maximum equatorial radius, ms is the mass of the satellite, and R is the orbital distance of the satellite. The parameterization is completed by a third non-dimensional number, R/a, representing the ratio of satellite distance to equatorial radius. For non-zero qtid, the calculated figure changes from a axisymmetric about the rotational axis to a fully triaxial spheroid.

From our CMS simulations, we find the zonal Jn and tesseral Cnm and Snm gravitational harmonics. These harmonics sample slightly different regions of the planet. Figure 3 shows the relative weight of the contribution to the low-order Jn and Cnm as a function of non-dimensional radius. In the case of Jupiter and the Galilean satellites, qrot ≫ qtid, and tidal perturbations from multiple moons can be linearly superposed. Moreover, all of the gravitationally important moons have orbits with nearly zero inclination. This allows us to treat a simplified case where we consider a single satellite with a fixed position in the equatorial plane, at angular coordinates \( \mu = \cos \theta = 0 \) (where \( \theta \) is the satellite’s colatitude measured from Jupiter’s pole), and \( \phi = 0 \) (the satellite’s Jupiter-centered longitude). By symmetry, this configuration constrains \( S_{nm} = 0 \), and the tidal Love numbers can then be determined from

\[ k_{nm} = -\frac{2}{3} \frac{(n + m)!}{(n - m)!} \frac{C_{nm}}{P_n^m(0)} \left( \frac{a}{R} \right)^{2-n}, \]  

(6)

where \( P_n^m(0) \) is the associated Legendre polynomial evaluated at \( \mu = 0 \). In this paper, we perform independent calculations for the three satellites with the largest qtid: Io, Europa, and Ganymede (see Table 1).

For a tidally perturbed non-rotating body, \( k_{nm} \) is degenerate with respect to n. However, Wahl et al. (2016) find that a large rotational bulge breaks this degeneracy. This leads to unexpectedly large values for some of the higher-order \( k_{nm} \). In the case of a rapidly rotating gas giant, the predicted splitting of the \( k_{nm} \) and shift of \( k_{22} \) is well above the expected uncertainty of Juno measurements.

### 4. RESULTS

#### 4.1. State Mixing for Static Love Numbers

In the CMS method applied to tides, we calculate the tesseral harmonics \( C_{nm} \) directly, and the Love numbers \( k_{nm} \) are then calculated using Equation (6). For the common tidal problem where \( q_{\text{tid}} \) and \( q_{\text{rot}} \) are carried to first-order perturbation only, this definition of \( k_{nm} \) removes all dependence on the small parameters \( q_{\text{tid}} \) and \( a/R \), which is convenient for calculating the expected tidal tesseral terms excited by satellites of arbitrary masses at arbitrary orbital distances. However, the high-precision numerical results from our CMS tidal theory reveal
that, when \( q_{\text{tot}} \approx 0.1 \), as is the case for Jupiter and Saturn, the mixed excitation of tidal and rotational harmonic terms in the external gravity potential has the effect of introducing a small—but significant—dependence of \( k_{22} \) on \( a/R \); (see Figure 6). In the absence of rotation, the CMS calculations yield results without any state mixing, and the \( k_{nm} \) are, as expected, constant with respect to \( a/R \). It is important to note this effect on the static Love numbers, because, as we discuss below, dynamical tides can also introduce a dependence on \( a/R \) via differing satellite orbital frequencies.

### 4.2. Calculated Static Tidal Response

The calculated zonal harmonics \( J_n \) and tidal Love numbers \( k_{nm} \) for all of the Jupiter models with Io satellite parameters are shown in Table 3. Our preferred Jupiter model has a calculated \( k_2 \) of 0.5900. In all cases, these Love numbers are significantly different from those predicted for a non-rotating planet (see Table 4). Figure 4 shows the different tesseral harmonics \( C_{nm} \) calculated with and without rotation. For a non-rotating planet with identical density distribution to the preferred model, we find a much smaller \( k_{22} = 0.53725 \). Juno should, therefore, be

Note. Model parameters from Hubbard & Militzer (2016). \( S \) is the specific entropy for the adiabat through the inner or outer H–He envelope. \( M \) is the mass of heavy elements included in each layer. Each model matches the observed \( J_2 = 14696.43 \times 10^6 \) (Jacobson 2003) JUP230 orbit solution, to six significant figures. Models are denoted as “DFT-MD” for the equation of state based on ab initio simulations, or “SC” for the Saumon et al. (1995) equation of state, with a number denoting entropy below the helium demixing layer. The number of models denoted with \( (J_4) \) also matches observed \( J_4 = -596.31 \times 10^6 \). The model denoted (equal-Z) is constrained to have the same metallicity in inner and outer portions of the planet. Our preferred interior model is shown in bold face.

![Figure 2](image1.png)  
**Figure 2.** Density structure of Jupiter models (the planetary unit of density \( \rho_\text{pu} = M/a^3 \)). The red curve shows our preferred model, based on ab initio calculations. The blue curve uses the Saumon and Chabrier equation of state. The shaded area denotes the helium-demixing region. Both models have \( N = 511 \) layers and a dense core within \( r = 0.15a \). Constant core densities are adjusted to match \( J_2 \), as measured by fits to Jupiter flyby Doppler data (Jacobson 2003).

![Figure 3](image2.png)  
**Figure 3.** Top: relative contribution of spheroids to external gravitational zonal harmonic coefficients, up to order 8. Bottom: relative contribution of spheroids to external gravitational tesseral coefficients, up to order 4. Tesseral moments of the same order (i.e., \( C_{31} \) and \( C_{33} \)) have indistinguishable radial distributions. Values are normalized so that each harmonic integrates to unity. The shaded area denotes the helium-demixing region.

4.2. Calculated Static Tidal Response

The calculated zonal harmonics \( J_n \) and tidal Love numbers \( k_{nm} \) for all of the Jupiter models with Io satellite parameters are shown in Table 3. Our preferred Jupiter model has a calculated \( k_2 \) of 0.5900. In all cases, these Love numbers are significantly different from those predicted for a non-rotating planet (see Table 4). Figure 4 shows the different tesseral harmonics \( C_{nm} \) calculated with and without rotation. For a non-rotating planet with identical density distribution to the preferred model, we find a much smaller \( k_{22} = 0.53725 \). Juno should, therefore, be

Note. Tidal response of preferred interior model “DFT_MD 7.13,” with \(q_{\text{dial}}\) and \(R/\mu\) for three large satellites, and for a “non-rotating” model with \(q_{\text{dial}} = 0\). In bold face is the same preferred model as in 3.
\(^a\) Non-rotating model has an identical density structure to rotating model.

---

Figure 4. The tesseral harmonic magnitude \(C_{nm}\) for the “DFT_MD 7.13” Jupiter model, with a tidal perturbation corresponding to Io at its average orbital distance. Black: the values calculated with Jupiter’s rotation rate; red: the values for a non-rotating body with identical layer densities. Positive values are shown as filled and negative as empty.

---

Figure 5. Predicted \(k_2\) Love numbers for Jupiter models plotted against \(J_\alpha\). The favored interior model “DFT_MD_7.13,” with a tidal perturbation from Io, is denoted by the red star. The other interior models, with barotropes based on the DFT-MD simulations (blue), have \(k_2\) forming a linear trend with \(J_\alpha\). Models using the Saumon and Chabrier barotrope (green) plot slightly above this trend. The \(k_2\) for a single model “DFT_MD_7.13,” with tidal perturbations from Europa and Ganymede (yellow), show larger differences than any resulting from interior structure.

---

In addition, we find small, but significant, differences between the tidal responses of Jupiter’s most influential satellites. Figure 5 shows the calculated \(C_{nm}\) for simulations with Io, Europa, and Ganymede. We attribute the dependence on orbital distance to the state mixing described in Section 4.1. This leads to a difference in \(k_{22}\) between the three satellites (Table 4) that may be discernible in Juno’s measurements.

5. CORRECTION FOR DYNAMICAL TIDES

5.1. Small Correction for Non-rotating Model of Jupiter

The general problem of the tidal response of a rotationally distorted liquid Jovian planet to a time-varying perturbation from an orbiting satellite has not been solved at a precision equal to that of the static CMS tidal theory of Wahl et al. (2016) and this paper. However, an elegant approach based on forced-oscillation theory has been applied to the less-general problem of a non-rotating Jovian planet perturbed by a satellite in a circular orbit (Vorontsov et al. 1984). Let us continue to use the spherical coordinate system \((r, \theta, \phi)\), where \(r\) is radius, \(\theta\) is colatitude, and \(\phi\) is longitude. Assume that the satellite is in the planet’s equatorial plane \((\theta = \pi/2)\) and orbits prograde at angular rate \(\Omega_\phi\). For a given planet interior structure, Vorontsov et al. (1984) first obtain its eigenfrequencies \(\omega_{nm}\) and orthonormal eigenfunctions \(u_{nm}(r, \theta, \phi)\), projected on spherical harmonics of degree \(\ell\) and order \(m\) (the index \(n = 0, 1, 2, \ldots\) is the number of radial nodes of the eigenfunction). Note that, in their convention, oscillations moving prograde (in the direction of increasing \(\phi\)) have negative \(m\), whereas some authors, e.g., Marley & Porco (1993) use the opposite convention.

Treating the tidal response as a forced-oscillation problem, using Equation (24) of Vorontsov et al. (1984), the vector tidal displacement \(\xi\) then reads

\[
\xi(r, t) = -\sum_{\ell,m,n} \frac{\left(\mathbf{u}_{\ell,m,n} \cdot \nabla \psi_{nm}(r)\right)}{\ell,m,n} e^{-i\ell \Omega_\phi t} e^{-i\omega_{nm} t},
\]

(7)
where \( u_{\ell,m,n} \cdot \nabla \psi_{\ell m} \) is the integrated scalar product of the vector displacement eigenfunction \( u_{\ell m n}(r, \theta, \phi) \) and the gradient of the corresponding term of the satellite’s tidal potential \( \psi_{\ell m}(r, \theta, \phi, t) \), viz.

\[
(u_{\ell,m,n} \cdot \nabla \psi_{\ell m}) = \int dV \rho_0(r) (u_{\ell,m,n} \cdot \nabla \psi_{\ell m}).
\] (8)

The integral is taken over the entire spherical volume of the planet, weighted by the unperturbed spherical mass density distribution \( \rho_0(r) \).

Vorontsov et al. (1984) then show that, for the nonrotating Jupiter problem, the degree-two dynamical Love number \( k_{2,d} \) is determined to high precision (\( \sim 0.05\% \)) by off-resonance excitation of the \( \ell = 2, m = 2, n = 0 \) and \( \ell = 2, m = -2, n = 0 \) oscillation modes, such that

\[
k_{2,d} = \frac{\omega_{2,20}}{\omega_{2,20} - (2\Omega_S)^2} k_2,
\] (9)

noting that \( \omega_{2,20} \) and \( \omega_{2,-20} \) are equal for nonrotating Jupiter (all Love numbers in the present paper, written without the subscript \( d \), are understood to be static). For a Jupiter model fitted to the observed value of \( J_2 \), Vorontsov et al. (1984) set \( \Omega_S = 0 \) to obtain \( k_2 = 0.541 \), which is within 0.7% of our nonrotating value of 0.53725 (see Table 4). Setting \( \Omega_S \) to the value for Io, Equation (9) predicts that \( k_{2,d} = 0.547 \), i.e., the dynamical correction increases \( k_2 \) by 1.2%. This effect would be only marginally detectable by the Juno measurements of Jupiter’s gravity, given the expected observational uncertainty.

5.2. Dynamical Effects for Rotating Model of Jupiter

For a more realistic model of Jupiter tidal interactions, the dynamical correction to the tidal response might be larger—and therefore, more detectable. We have already shown (Table 4) that inclusion of Jupiter’s rotational distortion increases the static \( k_2 \) by nearly 10% above the non-rotating static value for a spherical planet. In this section, we note that Jupiter’s rapid rotation may also change Jupiter’s dynamic tidal response, by a factor that remains to be calculated.

In a frame co-rotating with Jupiter at the rate \( \Omega_p = 2\pi/35730 \text{ s} \), the rate at which the subsatellite point moves is obtained by the scalar difference \( \Delta \Omega = \Omega_S - \Omega_p \), which is negative for all Galilean satellites. Thus, in Jupiter’s fluid-stationary frame, the subsatellite point moves retrograde (it is carried to the west by Jupiter’s spin). For Io, we have \( \Delta \Omega = -1.35 \times 10^{-4} \text{ rad s}^{-1} \). Jupiter’s rotation splits the \( \omega_{2,\pm 20} \) frequencies (Vorontsov & Zharkov 1981), such that \( \omega_{2,-20} = 5.24 \times 10^{-4} \text{ rad s}^{-1} \) and \( \omega_{2,20} = 8.73 \times 10^{-4} \text{ rad s}^{-1} \). The oscillation frequencies of the Jovian modes closest to tidal resonance with Io are higher than the frequency of the tidal disturbance in the fluid-stationary frame, but are closer to resonance than in the case of the non-rotating model considered by Vorontsov et al. (1984).

An analogous investigation, for tides on Saturn raised by Tethys and Dione, yields results similar to the Jupiter values: tides from Tethys or Dione are closer to resonance with normal modes for \( \ell = 2 \) and \( m = 2 \) and \( m = -2 \). Because our static value of \( k_2 \) for Saturn (Wahl et al. 2016) is robust to various assumptions about interior structure, and agrees well with the value deduced by Lainey et al. (2016), we have, thus far, no evidence for dynamical tidal amplification effects in the Saturn system.

Unlike the investigation of Lainey et al. (2016), which relied on analysis of astrometric data for Saturn satellite motions, the Juno gravity investigation will attempt to directly determine Jupiter’s \( k_2 \) by analyzing the influence of Jovian tesseral-harmonic terms on the spacecraft orbit. A discrepancy between the observed \( k_2 \) and our predicted static \( k_2 \) would indicate the need for a quantitative theory of dynamical tides in rapidly rotating Jovian planets.

6. CONCLUSIONS

Our study has predicted the static tidal Love numbers \( k_{nm} \) for Jupiter and its three most influential satellites. These results have the following features: (a) They are consistent with the most recent evaluation of Jupiter’s \( J_2 \) gravitational coefficient; (b) they are fully consistent with state-of-the-art interior models (Hubbard & Militzer 2016) incorporating DFT-MD equations of state, with a density enhancement across a region of H–He immiscibility (Morales et al. 2013); (c) we use the non-perturbative CMS method for the first time to calculate high-order tesseral harmonic coefficients and Love numbers for Jupiter.

The combination of the DFT-MD equation of state and observed \( J_2 \) strongly limit the parameter space of pre-Juno models. Within this limited parameter space, the calculated \( k_{nm} \) show minimal dependence on details of the interior structure. Despite this, our CMS calculations predict several interesting features of Jupiter’s tidal response that the Juno gravity science system should be able to detect. In response to the rapid rotation of the planet, the \( k_2 \) tidal Love number is predicted to be much higher than expected for a non-rotating body. Moreover, the rotation causes state mixing between different tesseral harmonics, leading to a dependence of higher-order static \( k_{nm} \) on both \( m \) and the orbital distance of the satellite. An additional, significant dependence on \( a/r \) is expected in the dynamic tidal response. We present an estimate of the dynamical correction to our calculations of the static response, but a full analysis of the dynamic theory of tides has yet to be performed.
