Keywords: bacteria; photosynthesis; light harvesting; reaction center; membrane proteins; membrane biogenesis; atomic force microscopy

Background: Photosynthesis relies upon interconnected pigment protein complexes to capture, transfer and utilize light energy.

Results: Aberrant forms of light-harvesting I (LH1) complex occur without the reaction center (RC); complete RC-LH1 complexes and isolated reaction centers occurred when LH1 levels were reduced.

Conclusion: The subunits of the RC-LH1 complex of Rhodobacter sphaeroides are assembled cooperatively.

Significance: This represents a paradigm for assembly of other purple bacterial photosystems.

Abstract

In the purple phototrophic bacterium Rhodobacter sphaeroides many protein complexes congregate within the membrane to form operational photosynthetic units consisting of arrays of light-harvesting LH2 complexes and monomeric and dimeric reaction center-light-harvesting 1-PufX (RC-LH1-PufX) ‘core’ complexes. Each half of a dimer complex consists of a RC surrounded by 14 LH1 αβ subunits, with two BCHls sandwiched between each αβ pair of transmembrane helices. We used atomic force microscopy (AFM) to investigate the assembly of single molecules of the RC-LH1-PufX complex using membranes prepared from LH2-minus mutants. When the RC and PufX components were also absent AFM revealed a series of LH1 variants where the repeating α₁β₁(Bchl)₂ units had formed rings of variable size, ellipses, and spirals and also arcs that could be assembly products. The spiral complexes occur when the LH1 ring has failed to close, and short arcs are suggestive of prematurely terminated LH1 complex assembly. In the absence of RCs we occasionally observed captive proteins enclosed by the LH1 ring. When production of LH1 units was restricted by lowering the relative levels of the cognate pufBA transcript, we imaged a mixture of complete RC-LH1 core complexes, empty LH1 rings and isolated RCs, leading us to conclude that once a RC associates with the first α₁β₁(Bchl)₂ subunit, co-
operative associations between subsequent subunits and the RC tend to drive LH1 ring assembly to completion.

In order to grow photosynthetically the purple bacterium *Rhodobacter (Rba.) sphaeroides* forms a highly invaginated intracytoplasmic membrane (ICM) where the components of the photosystem reside (1). Atomic Force Microscopy (AFM) studies of bacterial photosynthetic membranes have revealed the organization of photosynthetic complexes in ICM from *Rba. sphaeroides*; large areas of the peripheral light-harvesting LH2 complex are connected to reaction centre-light harvesting-1-PufX (RC-LH1-PufX) core complexes, thus providing an efficient light gathering and energy transmission network of bacteriochlorophylls (BChls) (2,3). Similar networks have been observed in other purple bacteria but with either monomeric core complexes mixed with the LH2 complex (4-6) or arrays consisting of only monomeric core complexes as in *Blastochloris (Bla.) viridis* (7); see (8,9) for reviews.

To our knowledge, the biogenesis of membrane protein complexes has not been investigated using AFM, despite the advantages of this approach in terms of visualizing single molecules in their native membrane environment, under liquid. More specifically, the assembly of the RC-LH1-PufX complex has not been investigated in detail. The 521 kDa RC-LH1-PufX dimer comprises 64 polypeptide components, 64 Bchl cofactors and 58 carotenoids (10,11), and it therefore presents a challenging target for assembly studies. It is known that the RC-H subunit is the first component that appears when highly aerated, almost unpigmented cells, are switched to the low aeration conditions that promote photosystem assembly (12), an observation consistent with earlier work (13), and that the PufX polypeptide is incorporated before the LH1 α and β polypeptides (12). A modular assembly mechanism was proposed for the LH1 complex as it enircles the RC (12,14), in which $\alpha_1\beta_1(Bchl)_2$ units are progressively added until the final stoichiometry of $\alpha_2\beta_2(Bchl)_5$ is reached in the case of the dimeric RC-LH1-PufX complex (10).

In order to accumulate sufficient levels of assembly products for biochemical and structural analyses it is sometimes necessary to perturb the latter stages of photosystem biogenesis. This strategy has been widely used to dissect the process of the Photosystem II assembly in the cyanobacterium *Synechocystis* 6803. Mutants lacking various subunits of Photosystem II accumulate distinct transient assembly intermediates (15), which allowed the identification of protein factors involved in Photosystem II biogenesis (16,17). In this work we simplified the analysis of AFM topographs by deleting the *pucBA* genes encoding LH2 polypeptides, and the *pufX* gene encoding the PufX component of the RC-LH1-PufX dimer, leaving a monomeric RC-LH1 as the sole remaining photosystem complex. The role of PufX in the assembly of the core complex will be addressed in future work. We also limited the production of LH1 subunits relative to RC polypeptides by removing a stem-loop structure between *pufA* and *pufL* (12) and analysed the effects of depleting LH1 levels. Finally, we analysed the further consequences of deleting genes encoding the RC L and M polypeptides, which leaves only the ‘empty’ LH1 ring.

A previous AFM study of LH1 complexes solubilized in detergent and then reconstituted into two-dimensional sheets had revealed a variety of distorted LH1 complexes, as well as incomplete rings, spirals and ‘C’ shaped arcs (18). To exclude the possibility of preparation-induced artefacts we developed a detergent-free membrane isolation procedure. AFM imaging of these membranes show that the combinations of mutations used have disrupted the normal developmental cues that guide the assembly and correct sizing of LH1; in the case of membranes isolated from the LH1-only mutant we observed variable ring sizes, rings distorted to either elliptical or more extreme morphologies, short arcs, incomplete rings and also spirals where the ring has failed to close. Reducing the levels of $\alpha_1\beta_1(Bchl)_2$ subunits resulted in a sub-population of isolated RCs which had no evidence of even a partial LH1 complex associated with them while the rest of the RC-LH1 complexes had a complete ring. These single molecule observations reveal complexities of photosystem assembly that would not be detected in ensembles by bulk electrophoretic or spectroscopic techniques. Our data indicate that the assembly of core complexes is driven largely by co-operative associations between $\alpha_1\beta_1(Bchl)_2$
subunits around the RC template. We propose a mechanism for formation of αβ(Bchl)₂ subunits and a sequence for their assembly round the RC.

**Experimental procedures**

*Strains and standard cell culture.* The following LH2-minus mutants of *Rba. sphaeroides* were used: DD13(pRKEK1), which produces only the LH1 complex and DD13(pRKEHWT) which produces a mixture of monomeric and dimeric core complexes (19) DD13(pRKEH10X') and DD13(pRKΔTΔX) (20), both make monomeric PufX-minus RC-LH1 core complexes, with the latter mutant lacking the stem-loop structure between *pufB* and *pufL*, that ensures a normal LH1:RC stoichiometry. Each of these mutants uses the DD13 background (19), in which both the *pucBA1* and *pufBALMX*, encoding polypeptides of the LH2 and RC-LH1-PufX core complexes respectively, are deleted. Conjugal transfer of the pRK plasmid variants into DD13 confers the LH1-only, PufX-plus RC-LH1 and PufX-minus RC-LH1 core phenotypes. All strains were grown in M22+ medium supplemented with casamino acids and vitamins. Semi-aerobic cultures of the LH1-only strain DD13(pRKEK1) and the PufX-minus strain DD13(pRKEH10X') were grown in the dark, using a shaking incubator at 140 rpm at 30°C, in conical flasks at 75% capacity. DD13(pRKEHWT) and DD13(pRKΔTΔX) were grown phototrophically in 1L Roux bottles, presparged with N₂, at RT with constant stirring at a light intensity of ~500 µmol m⁻² s⁻¹.

*Preparation of intracytoplasmic membranes.* ICM and membrane patches were prepared from DD13(pRKEK1) and DD13(pRKEH10X') by broadly the same methodology as in Olsen et al. 2008 (21). Briefly, cells were disrupted in a French press and the membranes separated on a discontinuous 15/40% w/w sucrose density gradient. 5 ODU @ 875nm of these membranes were then layered onto a 30/34/37/40/50% w/w sucrose discontinuous gradient and centrifuged in a Beckman SW41 rotor for 1 hour at 40,000 rpm, 4°C and the resultant bands collected. These detergent-free membranes were stored at -20°C until used for imaging. The detergent-treated DD13(pRKEK1) and DD13(pRKEH10X') membranes were prepared as above except that they were incubated for 30 min at RT with β-dodecylmaltoglucoside (β-DDM) (Glycon Biochemistry, GmbH Biotechnology, Germany) at a final concentration of between 0.1 mM and 0.2 mM (critical micelle concentration ~ 0.34 mM) and separated on a discontinuous 20/30/40/50% w/w, 10 mM HEPES, pH 7.5, 10 mM EDTA, 0.1/0.2 mM β-DDM sucrose density gradient in a Beckman SW41 rotor, 4 hours, 40,000 rpm at 4°C. The DD13(pRKΔTΔX) membrane preparation was incubated with β-DDM as above but then centrifuged through a 20/30/40/50% discontinuous sucrose gradient containing 0.5 mM n-tetradecyl-β-D-maltopyranoside (TD) (Anatrace, Affymetrix, USA). The membrane bands collected were diluted, with 20 mM HEPES, pH 7.5 buffer, between 10- and 20-fold prior to adsorption onto mica substrates (Agar Scientific) and allowed to adsorb for at least 60 min at RT.

*Atomic force microscopy (AFM).* Standard Olympus TR800PSA SiN probes (Atomic Force GmbH, Mannheim, Germany), with a spring constant of 0.15 N/m and Si/SiN “SNL” probes (Bruker AFM Probes) with a spring constant of 0.12 N/m were used in a standard tapping mode liquid cell at operating frequencies of ~9 KHz, using a Nanoscope IV AFM and E scanner and a Nanoscope V Multimode 8 with E scanner. Peak Force tapping mode imaging was conducted using SNL probes, 0.24 N/m spring constant, 2 KHz operating frequency in a Nanoscope V Multimode 8 with E scanner. The images were recorded at scan frequencies of 0.5-1.0 Hz and subsequently analysed as described below.

Topographs were flattened and three-dimensional (3-D) representations generated using Bruker Nanoscope Analysis software (v1.4). Statistical analysis of high resolution topographs was performed using the same software to measure peak to peak of height profiles across individual molecules in line with the scan and orthogonal to it. Only clearly defined complexes were examined to produce the most accurate analysis. For the LH1 diameter measurements, the distance between the maximal protrusions of each side of the LH1 ring was taken (i.e. diameter corresponds to a ‘middle’ diameter, in between the inner and outer limits of the ring structure). To establish the presence of protein vs. lipid in low resolution images all heights were measured from the mica substrate.
Assembly of the RC-LH1-PufX core complex

Quantitative proteomic analysis of developing photosynthetic membranes. Total membrane proteins (30 µg by Bradford assay) from a pigmented membrane fraction previously identified as developing, immature membranes (1) were separated by SDS-PAGE ((NuPAGE 12%, 1 mm, Life Technologies, Carlsbad, CA, USA). After staining with colloidal Coomassie Blue, the gel was cut into 30 slices which were then incubated with trypsin (22). The extracted tryptic peptides were analysed by nanoLC -MS/MS and identified by database searching (23). Peptides mapping to core complex subunits PufL, PufM and PufA were quantified by comparison with the ion intensities of 3 pmol of peptide standards derived from the tryptic digestion of an artificial protein containing the relevant proteotypic peptide sequences (11).

Results

Aberrant assembly of the LH1 ring in the absence of PufX and RC complexes: the formation of variable ring sizes and morphologies, and the presence of short arcs, and linear LH1 assemblies.

Peak Force tapping AFM (PF-AFM) was used to image a representative range of membrane patches from the LH1-only mutant DD13(pRKEK1) at a resolution high enough to visualize the size and shape of the LH1 ring (Fig. 1). We note the lack of any protein within the majority of the LH1 complexes imaged which indicates that the RC H-subunit does not appear to associate with the LH1 complex in the absence of the RC L and M subunits (Fig. 1A & B).

The dimensions of the LH1 complexes were extracted from AFM topographs in orthogonal orientations in order to obtain a realistic assessment of the size and flexibility of the LH1 ring both with and without the RC. The data, summarized in Table 1, show that the LH1-only rings are smaller on average, width 9.9 ± 0.7 nm, height 10.6 ± 0.9 nm (S.D. n=21), in comparison with monomeric RC-LH1 core complexes, width 11.2 ± 0.6 nm, height 11.3 ± 0.6 nm (S.D. n=9).

In patches imaged to higher resolution (Fig. 1A-D) we identified several aberrant forms of LH1, including incomplete rings (blue boxes), spirals (green and white boxes), arcs (cyan boxes) and near linear features (magenta boxes). In panels A and B the membranes were prepared without using detergent, whereas the membrane piece in panel D had been prepared using sub-CMC levels of β-DDM, as detailed in Experimental Procedures. The appearance of many deformed LH1 complexes in both sets of membrane patches indicates that the method of membrane preparation has no influence on the morphology of the complexes (colored boxes, Fig. 1A-D). In the cases marked by the green and white box a gently curved row of αβ(Bchl)2 subunits is seen (Fig. 1B, and 1D respectively) making a continuous structure with the spirals. Short, almost linear structures (magenta boxes Fig. 1B) can be seen in the enlargement, Fig. 1C, which, like the incomplete rings, could be ‘stalled’ LH1 αβ(Bchl)2 oligomers that failed to polymerise sufficiently to form a closed complex. More examples of β-DDM detergent prepared membranes containing aberrant LH1 complexes, with distorted rings, incomplete rings, arcs and spirals are shown in Fig. 2. In total we observed 37 deformed LH1 complexes in both sets of membrane patches representing 304 LH1 complexes in total, whereas no such structures were observed in membranes from wild-type cells.

Aberrant assembly of the LH1 ring in the absence of PufX and RC complexes: occasional capture of unknown proteins within LH1 rings. An enlargement of the LH1-only membrane AFM data from Fig. 1A highlights three LH1 complexes, with corresponding colored height profiles, that show two encircled proteins compared with an empty LH1 ring (Fig. 3A). Inset is the topograph of an RC-LH1 complex showing the prominent topology of the RC-H subunit, which clearly protrudes much more than the captive proteins (Fig. 3B magenta section). The vertical dashed lines on the sections of Fig. 3B denote the highest points of the LH1 ring, which highlights the relatively low topology of the captive proteins, shown by the red and green sections, in relation to a RC-H subunit (magenta line). The much greater diameter of the LH1 complex surrounding the RC is also clear in this section. In contrast, when no protein is enclosed by LH1 the AFM probe penetrates more deeply into the LH1 interior (blue section), which is nevertheless 5.4 nm above the mica substrate suggesting that the interior of the complex is filled with lipid. Of 181 clearly defined complexes only 3 contained unambiguous central density,
indicating the presence of a captive protein. The results for LH1-only membranes prepared using mild detergents (Fig. 2 A & B) mirror those from entirely detergent-free preparations in Figs. 1 & 3, where of 123 complexes three contained central density consistent with captive proteins, and demonstrate that oligomerization of α1β1(Bchl)2 subunits can occasionally capture foreign proteins when the RC complex they normally encircle is absent.

**Aberrant membrane architecture in the absence of PufX and LH2 complexes: identification of LH1-only complexes.** Fig. 4A shows an ICM-derived patch prepared without detergent from an LH1+RC+ PufX- LH2- mutant, which assembles only monomeric RC-LH1 complexes. The AFM topographs show that the membrane consists mainly of well-ordered RC-LH1 monomers, however the lattice is interrupted in places (red arrows) by a surprisingly large number of empty LH1 rings of varying size. Inspection of the four scans prior to this image rules out the possibility of repeated scanning inducing the removal of the RC as there is no sign of an intact RC at the positions of the empty LH1 rings (Data not shown), which would be expected if AFM-induced damage had occurred. There is only one example of an LH1 ring with partial central density (white arrow), which is expected to represent RC-L and RC-M. A similar situation occurs in the membrane patch in Fig. 4B where two empty LH1 rings can be seen adjacent to intact RC-LH1 complexes; the two prior scans show no evidence of the RC within either of these LH1 rings. Elsewhere in the patch a number of RC-LH1 complexes lacking a H subunit occur (example indicated with white arrow).

The presence of empty LH1 rings in this PufX-LH2 mutant implies an excess of LH1 polypeptides over RC subunits. In order to address this issue we used quantitative proteomic analysis to determine the ratio of LH1 α to RC polypeptides in developing photosynthetic membranes of *Rhodobacter sphaeroides*. Our data show that the mean ratio of LH1 α to the RC-L and -M subunits in the membrane precursor fraction is 29:1. To put this in perspective, a ratio of 14:1 is necessary to form an RC-LH1-PufX dimer complex, as shown by a recent structural study (11). These mass spectrometry data clearly show that the biogenesis centres in *Rhodobacter sphaeroides* produce a molar excess of LH1 polypeptides over the RC components.

These data support the proposal that the empty LH1 complexes are the products of aberrant assembly. Empty LH1 complexes have also been observed in RC-LH1 only membrane patches prepared using β-DDM, see Fig. 5.

**Consequences of limited α1β1(Bchl)2 subunit production upon assembly of RC-LH1 core complexes.** In order to investigate the effects of restricting the number of LH1 subunits on assembly of core complexes, we used the ‘small core’ mutant DD13(pRKΔTΔX) (12). Here, deletion of a stem-loop between *pufA* and *L* genes lowers the levels of the LH1 *pufBA* transcript with respect to the RC-LH1 transcript encoded by *pufBALM*, with the effect that the absorbance of LH1 is lowered by ~43%, see Fig. 6B. In order to verify the presence of isolated, LH1-free RCs in these membranes we performed a biochemical analysis using rate-zone centrifugation of detergent-solubilized membranes, see Fig. 6A & C, which separates the complexes into an upper monomeric band and a lower dimeric core complex band. The small-core mutant DD13(pRKΔTΔX), Fig. 6C, consists largely of monomer core complexes with an LH1:RC ratio, approximated by the 875:805 absorbance ratio, of 3.6:1, compared to 6.2:1 in the WT control. The room temperature (RT) absorption spectrum of the well defined band above the monomer band indicates that it is composed of RCs with no accompanying LH1 complex. The yellow and orange bands at the top of both gradients are probably free carotenoids. These data are consistent with the presence of isolated RCs in the membrane of the LH1-limited DD13(pRKΔTΔX) mutant.

Membranes were prepared from photosynthetically grown cells of the LH1-limited mutant and analyzed by AFM. A high resolution topograph of a membrane patch (Fig. 7A) revealed that not only were complete RC-LH1 complexes present (magenta arrow) but also an isolated RC (white arrow) and empty LH1 rings (red arrow) could be imaged. The blue arrow shows a core complex with the RC-H subunit missing. Isolated RCs were observed in several AFM images and identified by their height profile in comparison with nearby core complexes, confirming the biochemical analysis shown in Fig. 6.
In the topograph there is a 2.3 nm height difference between the top of the RC-H subunit within an intact RC-LH1 complex (magenta arrow) and the RC-H of the isolated RC (white arrow). This height difference between the RC-only and the RC-LH1 complexes in the membrane is apparent because the C-terminal extrinsic region of the LH1α polypeptides in the ring normally raises the RC and the membrane bilayer off the mica surface (24). The visual absence of an LH1 ring around the white arrowed RC is supported by the 9.2 nm center-to-center distance to the magenta arrowed RC, whereas the equivalent distance between two well-resolved RC-LH1 complexes (marked with asterisks) is 13.3 nm. Fig. 7B is a diagrammatic representation of the height data for the two adjacent complexes in the topograph, an isolated RC (white arrow) that clearly has no LH1 encircling it and a complete RC-LH1 complex (magenta arrow).

Taken together with the biochemical analysis in Fig. 6, it is likely that the limited number of LH1 αβ1(Bchl)2 subunits are not shared equally among the RCs present; instead the assembly process favours completion of ring formation at the expense of some RCs, which are left with no LH1 complex.

Discussion
This work reports the first AFM study of RC-LH1 assembly, using membranes of Rba. sphaeroides containing only RC-LH1 or LH1 complexes prepared without the use of detergents, demonstrating that the various in situ aberrant LH1 forms are the product of perturbed assembly. Similar aberrant forms were previously observed in LH1 complexes purified from LH1-only membranes in 1% β-octyl glucoside and then reconstituted into 2D sheets by gradual removal of the detergent (18). In the present study, topographs of native membrane patches, prepared without detergents, reveal new insights into the factors that control the size and shape of LH1 complexes and drive the encirclement of the RC to completion. Single complexes within LH1-only and RC-LH1 membranes were imaged at a resolution sufficient for a comparison of the dimensions of the complexes; the LH1-only complex is smaller on average than the RC-LH1 monomeric core complex. Moreover, the variation in LH1 size, even in the presence of the RC, see Table 1, is an indicator of a very simple assembly system without rigid quality control.

Fig. 8A-C shows three LH1 complexes imaged at high resolution by AFM, together with schematic approximations of αβ1(Bchl)2 subunits showing how they might be arranged in each complex (Fig. 8D-F). The complete LH1 ring surrounding the RC (cyan oval, Fig. 8D) has been assigned as 16 αβ1(Bchl)2 subunits arranged in a roughly circular ring, in accordance with existing cryo-electron microscopy data showing that 16 LH1 subunits enclose a single RC (25). The presence of complete LH1 rings surrounding the Rba. sphaeroides RC in the same PufX mutant have been characterized by electron microscopy (26,27) and in a similar PufX LH2+ mutant by AFM (28). The empty LH1 ring (Fig. 8B) has been depicted as 15 αβ1(Bchl)2 subunits, (Fig. 8E), consistent with the slightly smaller diameter seen for such rings in AFM topographs (Fig. 3 and Table 1) whilst the large spiral (Fig. 8C) has been tentatively assigned as 18 αβ1(Bchl)2 subunits (Fig. 8F). As the predominant morphology of LH1-only complexes is a closed circular structure it is clear that the αβ1(Bchl)2 subunits naturally form curved arrays that tend to close once 15 or 16 subunits are joined together. Cryo-electron microscopy of Rhodospirillum rubrum LH1 complexes, reconstituted from αβ1(Bchl)2 units then dialysed to form 2D crystals, clearly shows sixteen-fold rings that are spectroscopically identical to the WT LH1 (29). Loach and co-workers have also shown in many studies (30-33) that Rba. sphaeroides LH1 αβ1(Bchl)2 (B820) units can self-assemble in vitro to form complete LH1 αβ16(Bchl)32 rings. In other work, they performed a series of reconstitution trials using LH1 polypeptides from Rba. sphaeroides and the RC from Rs. rubrum to form a spectroscopic photoreceptor complex (PRC) (34); from this result they proposed that there must be sites of recognition between the homologous LH1 and RC complexes that encourage a RC-LH1 complex to form. From these studies it seems clear that the LH1 complex naturally forms ring-shaped structures even in the absence of a RC template.

Although there is as yet no quantification of the forces involved in LH1 assembly, a recent force spectroscopy study by Liu et al. (35) quantified the ΔG for unfolding an LH2 αβ1(Bchl)3 subunit as 53 kcal mol⁻¹. We might
reasonably expect a similar ΔG for an LH1 \(\alpha_1\beta_1(Bchl)_2\) subunit, which suggests that in a typical LH1-only complex the cumulative small inter-subunit forces are a significant driving force for ring formation.

The presence of a spiral, such as that in Fig. 8C, indicates that in the absence of an RC template it only takes a minor perturbation of the nascent LH1, perhaps by crowding pressure of adjacent completed rings, to push one end out of alignment so that more subunits than are necessary are added, thus extending the complex into a spiral.

The most striking result of this study is the observation that partial LH1 rings do not occur when RCs are present, providing evidence that the RC clearly acts as a template for the developing LH1 complex. We suggest that, even in the absence of PufX, either a single \(\alpha_1\beta_1(Bchl)_2\) or a short \(\alpha_1\beta_1(Bchl)_2\) array, associates with the RC, see Fig. 9, and thereafter the cooperative forces of self-association between \(\alpha_1\beta_1(Bchl)_2\) subunits, and likely also with the RC, drive the efficient encirclement to form a completed core complex. This suggestion is consistent with earlier work, which studied the assembly of photosynthetic membranes by switching highly aerated cells with almost no pigment to conditions of low aeration in the dark that induce complex formation (12). Over the 6-hour timecourse of the experiment the RC-H subunit was detected before other components, followed by the PufX polypeptide, then a small level of LH1 \(\alpha\) and \(\beta\) polypeptides, which subsequently increases. Then, it was proposed that the earliest stages of assembly involve formation of a RC-PufX-(LH1\(\alpha_1\beta_1(Bchl)_2\)) complex, to which \(\alpha_1\beta_1(Bchl)_2\) units are progressively added, ultimately, encircling the RC (12).

The presence of empty LH1 rings in the RC-LH1 PufX- mutants implies an excess of LH1 polypeptides in this membrane. We tested this idea by using quantitative mass spectrometry to measure levels of the LH1 \(\alpha\) polypeptide in membrane biogenesis centres of \textit{Rba. sphaeroides} (1). The data show that in these centres there is a two-fold excess of LH1 \(\alpha\) relative to the level required to form a RC-LH1-PufX complex. It is possible that rather than having precisely metered delivery of pigments and proteins, the assembly system might be set up to favor an excess of LH polypeptides in order to ‘mop up’ Bchls that might otherwise be free in the membrane. This mechanism would avoid a potentially damaging situation in a photosynthetic organism where both light and oxygen may be present in sufficient levels to generate oxygen triplet states from unquenched Bchls. Spectroscopic studies have also shown the presence of empty LH1 rings; excitation transfer connectivity calculations (36) revealed that the membranes of the mutant R-26 of \textit{Rba. sphaeroides} were likely to contain significant numbers of empty LH1 rings. This proposal was subsequently supported by the AFM images of R-26 membranes (37). It should also be noted that an empty LH1 complex need not be inactive; it will still act as a light harvesting unit and as an excitation energy conduit between RC-LH1 complexes.

We had previously removed the stem-loop structure between the \textit{pufA} and \(L\) genes in the \textit{pufQBALMX} operon, in order to reduce the LH1:RC ratio (12); similar effects can also be achieved by progressive truncation of the C-terminal domain of the LH1\(\alpha\) polypeptide (38). Ensemble spectra in these previous studies showed a significant drop in the 875 nm absorbance arising from LH1 complexes relative to the 805 nm absorbance maximum of the monomeric Bchls of the RC. The absorbance spectra in the present work confirm the lowered levels of LH1 (Fig. 6B) and appear to suggest a disrupted assembly process where each of the RCs is only partially enclosed by LH1. However AFM imaging of membranes to the single molecule level reveals that the scarce LH1 units are not evenly distributed among the RCs; rather, the encircling process, once initiated appears to proceed to completion. The consequence is a population of fully encircled RCs, i.e. ‘intact’ RC-LH1, and also some isolated RCs with no LH1 attached. The appearance of an isolated RC band in rate-zonal centrifugation of solubilized membranes (Fig. 6C) of this small core mutant, but not in the WT equivalent solubilized membranes, supports this proposal. Core complexes lacking RC-H subunits could be a consequence of enhanced AFM tip induced nanodissection due to the absence of PufX, since similar observations have been made for membranes containing RC-LH1 PufX- core complexes of \textit{Rba. sphaeroides} (28). Furthermore the 3D crystal structure of the dimeric core
Assembly of the RC-LH1-PufX core complex

complex (11) shows a very clear association of the N-terminal region, residues 21-30, with the H-subunit, which must be stabilizing the dimer complex as N-terminal truncation studies have led to monomer cores being produced (39,40). But the presence of empty LH1 rings is somewhat surprising in a mutant that produces insufficient α1β1(Bchl)2 subunits to encircle every RC complex and is indicative of a very simple assembly process with little quality control.

The presence of ‘captive’ proteins within the LH1 complexes in the LH1-only mutant highlights the non-specific nature of the assembly process and demonstrates that in the absence of the reaction center template, LH1 subunits can assemble around another membrane protein of approximately the correct dimensions. Candidates for such proteins include the bacteriochlorophyll synthase BchG, which is predicted to have up to 8 transmembrane helices (41), and LhaA, an assembly factor for core complexes, predicted to have 12 transmembrane helices (42). These proteins are expected to be associated with the LH1 assembly process, but usually the RC L and M polypeptides would be present and favorable interactions between the α1β1(Bchl)2 subunits and the RC-L, -M & -H subunits would minimize the chances of LH1 forming around any other membrane protein. At this time we do not know the actual role of LhaA in the assembly of the core complex, although it has been proposed to be a bacteriochlorophyll delivery export permease (42). When lhaA is deleted levels of LH1 complex are significantly reduced, 5-10 fold, in comparison with the WT but RC assembly was largely unaffected (43). However the fact that some core complex does correctly assemble in the absence of LhaA indicates that while this protein greatly enhances assembly, it is not absolutely essential.

These data are consistent with the notion that the core complex of *Rba. sphaeroides* is the product of an assembly process in which cooperative hydrophobic and hydrophilic associations between the various polypeptides heavily bias the system towards formation of complete rings of LH1 around the RC template.
Assembly of the RC-LH1-PufX core complex

Figure Legends

Figure 1. LH1-only membrane patches in 3D representation showing aberrant complexes.
A, B, Membrane patches produced with no detergent treatment. C, Gallery of close-ups of boxed complexes in panel A and B with black line overlays showing the shape of the aberrant complexes and a grey disc denoting a captured protein in the red boxed complex. D, Membrane patch prepared using sub-
Assembly of the RC-LH1-PufX core complex

CMC levels of β-DDM. The white boxed complex is a spiral and the blue boxed complex is an open ring. The data in panel B and D have been treated with a low pass filter to reduce noise.

Figure 2. LH1-only membrane patches prepared using sub-CMC concentration β-DDM detergent in 3D representation showing aberrant complexes.
A, a piece of membrane showing a variety of aberrant LH1 complexes including an incomplete ring, blue arrow, arcs, cyan arrows and captive proteins, red arrows. B, a particularly well resolved captive protein with high topology, red arrow. C, examples of spiral complexes, white arrows. D, further examples of spiral complexes, white arrows. The image data have been treated with a low pass filter to reduce noise.

Figure 3. Putative captive proteins enclosed by LH1 rings.
A, Close-up of the LH1-only membrane in Fig. 1A; sections were taken across three LH1 complexes, one across an empty LH1 ring (blue line), and two across rings with a central density (red and green sections). The inset shows a topograph of a monomeric RC-LH1 (no PufX) complex for comparison purposes. B, Sections taken across the LH1 complexes shown in A; the magenta section was taken across an RC-LH1 complex from a separate sample of membranes containing monomeric RC-LH1 complexes. The vertical dashed lines indicate the highest points of the LH1 ring. The image data have been treated with a low pass filter to reduce noise; the section data have not been filtered.

Figure 4. 3D representations of RC-LH1 membrane patches showing empty LH1 rings.
A, empty LH1 rings (red arrows) within an RC-LH1 array; one core complex (white arrow) has lost its H-subunit probably as a result of the scanning by the AFM tip. B, a less well defined membrane patch where two prominent empty LH1 rings can be seen beside three core complexes as well as some nanodissected cores, of which the best example is indicated by the white arrow. The data have been treated with a low pass filter to reduce noise.

Figure 5. 3D representations of RC-LH1 membrane patches prepared using sub-CMC concentration β-DDM detergent showing empty LH1 rings.
A, a membrane patch of monomeric RC-LH1 complexes where most of the H-subunits are missing revealing the L- and M- subunits; two clear empty LH1 rings are denoted by the red arrows. B, a less well resolved patch of RC-LH1 complexes showing a small, ~ 8 nm diameter, empty LH1 ring, red arrow.

Figure 6. Analysis of the absorption and sedimentation behavior of solubilized complexes from membranes prepared from the RC-LH1 and LH1-limited mutants.
A, 2D RT NIR absorbance spectra of solubilized complexes of the LH1-limited DD13(pRKEHWT) mutant at 2 mm intervals through a discontinuous sucrose density gradient, where blue = no absorption and the spectrum through to red = increasing levels of absorption, aligned with a photograph of the gradient. B, RT NIR absorption spectra of DD13(pRKEHWT) and DD13(pRKΔTΔX) membranes normalized to the RC 805 nm band. C, 2D RT NIR absorption spectra of solubilized complexes of the LH1-limited mutant, DD13(pRKΔTΔX), aligned with a photograph of the gradient.

Figure 7. AFM analysis of a membrane patch prepared from the LH1-limited mutant DD13(pRKATAX).
A, 3D representation of a membrane patch exhibiting examples of an intact RC-LH1 complex, (magenta arrow), an isolated RC (white arrow), an RC-LH1 complex missing the H-subunit (blue arrow) and an empty LH1 ring (red arrow). B, schematic diagram to illustrate the expected height difference of an isolated RC, which would rest directly upon the mica substrate, in comparison with an intact RC-LH1 complex where the C-terminal region of the LH1 ring rests on the mica, holding the RC above it.

Figure 8. Three individual complexes and cartoons of their assigned composition.
Assembly of the RC-LH1-PufX core complex

A, an RC-LH1 core complex, B, an LH1 complex, C, an aberrant spiral LH1 complex. D, cartoon of an RC, cyan oval, surrounded by 16 $\alpha_1\beta_1$(Bchl)$_2$ subunits. E, a slightly distorted ring of 15 $\alpha_1\beta_1$(Bchl)$_2$ subunits. F, a spiral composed of 18 $\alpha_1\beta_1$(Bchl)$_2$ subunits.

**Figure 9. A schematic representation of the assembly system of *Rhodobacter sphaeroides* light harvesting complexe 1 and RC-LH1 core complexes.**

In the absence of LH2 and PufX polypeptides the pigments and polypeptides that comprise LH1 are still inserted into the membrane and self assemble into $\alpha_1\beta_1$(Bchl)$_2$ subunits, these associate together to form LH1 complexes in the absence of RCs or predominantly complete core complexes in the presence of RCs. Aberrant forms of LH1, i.e. varying ring size, arcs and spirals, occur in the absence of the RC template.

**Table 1. The average diameter of the LH1 ring, with and without the RC when prepared with and without detergents.**

|                  | Width (nm) | Height (nm) | Rings measured |
|------------------|------------|-------------|----------------|
| LH1-only with detergent | 10.1 ± 0.9 | 10.0 ± 1.6  | $n = 61$       |
| RC-LH1 with detergent    | 11.2 ± 0.5 | 11.5 ± 0.6  | $n = 12$       |
| LH1-only no detergent   | 9.9 ± 0.7  | 10.6 ± 0.9  | $n = 21$       |
| RC-LH1 no detergent    | 11.2 ± 0.6 | 11.3 ± 0.6  | $n = 9$        |

**Table Legend**

Table 1. The average diameter and standard deviation of the LH1 ring, with and without the RC, in line with the scan direction (Width) and orthogonal to the scan direction (Height). The diameter was measured between the highest points of the ring, i.e. the average ring diameter. There is no significant difference in the dimensions regardless of whether detergent has been used in the preparation of the membrane samples. The smaller number of diameters measured of core complexes represents the difficulty in obtaining AFM tips that are sufficiently sharp to resolve the ring when it is in such close proximity to the protruding H-subunit.
