(Dated: April 28, 2009)

We report the systematic investigations of the oscillation of the Josephson vortex (JV) flow resistance in Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ micro-fabricated junctions with various geometries and superconducting anisotropy parameters. As the applied magnetic field parallel to the $ab$-plane is increased, oscillation with a period corresponding to a $\phi_0/2$ par atomic Josephson junction changes to oscillation with a doubled period. This crossover is scaled by both the junction length and the anisotropy parameter, indicating that the bulk inductive coupling that favors the triangular JV lattice is replaced with the surface deformation energy as the dominant interaction for a JV lattice. These results suggest that the in-phase square JV lattice is pronounced at a higher magnetic field in a smaller and more anisotropic sample.

Highly anisotropic high-$T_c$ superconductors (HTSC) such as Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ (Bi2212) are well described as stacks of weakly coupled Josephson junctions (JJ’s) that consist of CuO$_2$ superconducting and charge reservoir block layers referred to as intrinsic Josephson junctions (IJJ’s). Not only the inductive couplings but also the capacitive couplings between the stacked Josephson junctions are responsible for such peculiar properties of JJ’s as multiple branches in the current-voltage ($IV$) characteristics and the longitudinal Josephson plasma mode. Rich collective excitation phenomena attributed to these couplings among identical stacked junctions can be adopted for investigating physics of HTSC and also promise us potentials for future device applications.

In the magnetic field parallel to the $ab$ plane, where Josephson vortices (JV’s) quantized as a unit of $\phi_0 = \hbar/2e$ are induced, various static and dynamic arrangements of JV’s are expected. The variety of phenomena is given by the couplings between the adjacent JJ’s, which make JJ’s a sharp contrast with artificially stacked JJ’s. The other characteristic features of the JV system in parallel magnetic fields have been found in the $IV$ characteristics of the Josephson plasma resonance, and etc.

Recently, Ooi et al. found a periodic oscillation of the JV flow resistance with a period of $\phi_0/2$ in Bi2212 IJJ’s with widths of 20–50 $\mu$m as a function of the magnetic field. They interpreted this is due to the coherent flow of the triangular JV lattice. Subsequently, Koshelev and Machida explained the oscillation by calculating the JV flow resistance by taking the surface barrier effect into consideration. In this model, since the surface barrier introduced by the boundary condition at the junction edges only influences the positions of JV’s close to the surfaces, a bulk property (triangular JV lattice) is probed by the surface current. Reducing the junction width to $\sim \mu$m is expected to make the surface barrier effect compete with the bulk inductive coupling between the JV arrays in neighboring layers and result in drastically different phenomena. In smaller junctions $< 10 \mu$m, the authors found oscillations with the doubled period $\phi_0$ at high magnetic fields and Hatano et al., reported the $\phi_0$ oscillation in a sub-micron junction. Motivated by our works, Machida and Koshelev proposed advanced calculations that the triangular and the square JV lattices appear alternatively as a function of magnetic field and that the square lattice is more favorable for higher magnetic field and in samples with smaller widths. Since the square JV lattice is a result of in-phase locked oscillation of the Josephson currents of the stacked JJ’s, realization of a square JV structure has been considered as a central issue for an electromagnetic radiation from JJ. Although recently reported strong terahertz emission from JJ’s in the absence of applied magnetic field is attributed to the size-restricted cavity resonance of the rather large mesas ($\sim 100\mu$m), tuning excited wavelength by JV lattice like a field tunable photonic crystal is a next goal of the IJJ emitter.

In this paper, we present the experimental results of the JV flow resistance and $IV$ characteristics in Bi2212 micro-structured single crystals with dimensions of 1–6 $\mu$m more clearly and systematically than in the previous work. In the smaller samples and at higher fields, we found periodic oscillation of the JV flow resistance with the period of the $\phi_0$ instead of $\phi_0/2$ as argued by the theories. The results clearly indicate that the crossover of the two oscillations is well tuned by both the superconducting anisotropy parameter and the junction size, which may prove formation of the square JV lattice in the static and slowly moving dynamic states.

Bi2212 single crystals grown with the traveling floating method were fabricated into bridge-shaped mesoscopic junctions with a focused ion beam (FIB) machine SMI2050MS (SII NanoTechnology Inc.). The fabrication details are described in Ref. Here, we report the results of seven junctions obtained from different slightly overdoped crystals as listed in Table. $T_c$’s are in the range of 84 – 90 K. External magnetic fields were applied by split pair superconducting magnets that generate a
horizontal magnetic field up to 80 kOe. Rotating the magnetic field around the \(ab\)-plane with a high precision rotator, \(c\)-axis resistance suddenly increases in the vicinity of the \(ab\)-plane. This resistance is attributed to the Josephson vortex flow resistance, and the lock-in state without pancake vortices is realized in this angle range. We set the field alignment parallel to the \(ab\)-plane with an accuracy of 0.01 degree.

Figures 1(a) and (b) represent the magnetic field dependencies of zero-current differential \(c\)-axis resistivity \(\rho_c = LW/t \cdot dV/dI\rangle_{I=0}\) at 60 K in sample B19 and P52, respectively. The data were derived from \(IV\) characteristics measured under external magnetic fields parallel to the \(ab\)-plane changed step by step. This method for evaluation of the \(JV\) feature is less ambiguous than the method with the ohmic resistance \(V/I\). The \(\rho_c\) in P52 smoothly increases below 7 kOe with increasing field from zero and then begins to oscillate with an oscillation center monotonically increasing, as shown in Fig. 1(b). Oscillation period \(H_p\) is 1.2 kOe, which approximately coincides with adding a half flux quantum \(\phi_0/2\) to a \(JV\) array in the block layer as \(H_0/2 = \phi_0/2Ls = 1.3\) kOe for P52, where \(s = 15\) Ås is the periodicity of the CuO\(_2\) double layer of Bi2212. This oscillation is quite similar to the previous results. The boundary effect for the triangular \(JV\) lattice is considered to be enhanced when the number of \(JV\)’s in a layer corresponds to either integer \((H/H_0 = k;\) full-integer matching) or half odd integer \((H/H_0 = k + 1/2;\) half-integer matching) due to matching of the periodicity of the \(JV\) lattice with the junction width for both two cases. These two matchings yield the oscillation with period of \(H_0/2\) and the bottom at \(H/H_0 = k\) and \(k + 1/2\).

With increasing magnetic field, the full-integer matching was diminished above 25 kOe and finally disappears above 40 kOe, while the half-integer matching does not change to 50 kOe. As a result, \(H_p\) becomes 2.43 kOe, which is twice the value of the \(H_p\) below 35 kOe and close to the \(H_0\) value of 2.50 kOe. This crossover from \(\phi_0/2\) to \(\phi_0\) oscillation was observed in a lower field region in a sample with smaller \(L\). Figure 1(a) shows a \(\rho_c - H\) curve in B19 with \(L = 1.9\) µm. \(\phi_0\) oscillation was certainly observed above 20 kOe, and only a small dip at \(H/H_0 = 2\) was found as a remnant of the \(\phi_0/2\) oscillation, as shown in the inset of Fig. 1(a).

Since linear \(IV\) characteristics were observed even in the low current limit as displayed in Fig. 2(a), it was implied that there is no true critical current in IJJ with \(JV\) lattices. This makes a remarkable contrast with an ordinary vortex system under the \(c\)-axis magnetic field for HTSC, where a super-linear increase in voltage in \(IV\) characteristics is regarded as the critical current. In order to compare with theoretically-derived field dependencies of critical current density \(J_c(H)\), the current \(I_0(H)\) at which the induced voltages along the junction are 2 mV is plotted as a function of magnetic field at various temperatures in Fig. 2(b). At 75 K below 15 kOe, \(I_0(H)\) oscillates with a period of \(H_0/2\) as proposed in Ref. 12 for \(J_c(H)\), while \(I_0(H)\) above 35 kOe shows oscillation with the period being \(H_0\) as well as \(\rho_c(H)\). The behavior of \(I_0(H)\) in the high field region turns to be similar to \(J_c(H)\) in a single Josephson junction (Fraunhofer pattern) that has local maxima at fields corresponding to

### Table I: List of samples.

| \(L\) | \(W\) | \(t\) | \(H_p\) | \(H_s\) | \(H_{1/2}\) | \(\gamma\) |

Section shows temperature dependence of anisotropy parameter \(\gamma\) obtained by Eq. (1).

\[
H_{1/2} = \frac{\phi_0 L}{2\pi \gamma s^2}.
\]

In order to extract generic boundary effect from our results in many samples with various oxygen concentrations, the sample specific parameter \(\gamma\) should be taken from measurable parameters. The comparison between the \(ab\)-plane resistance before FIB fabrication the \(c\)-axis resistance does not work in this case because oxygen would be reduced during FIB fabrication in the vacuum and implanted gallium ions may damage the junction. These influences are more serious in junctions with widths less than 5 microns. To obtain the anisotropy parameter in the exactly same situation as the sample, we use the formation of the dense triangular JV lattice, which is considered necessary for \(\phi_0/2\) oscillation. Using a minimum field for triangular dense JV lattice \(H_{tr} = 1.33\phi_0/2\pi \gamma s^2\) we obtain a simple relation:

\[
H_{1/2}/H_{tr}^2 = 0.736 \frac{2\pi s L}{\phi_0} = 3.35[1/\mu \text{mT}]L[\mu \text{m}],
\]

where the magnetic fields are given in the unit of Tesla. Assuming that \(H_{tr}\) corresponds to \(H_s\), the bare boundary effect for JVs may be extracted from the results.

Figure 3 shows the values of \(H_{1/2}/H_s^2\) as a function of junction length \(L\). \(H_{1/2}/H_s^2\) is roughly proportional to \(L\). \(H_{1/2}\) and \(H_s\) were obtained by extracting \(\delta R_1\) and \(\delta R_2\) from the resistance minima and maxima, as shown in the inset of Fig. 3. \(\delta R_1\) and \(\delta R_2\) are given by subtracting \(R_{min,1}\) the smooth curves connecting resistance minima at \(H/H_0 = k + 1/2\), and \(R_{min,2}\) from \(R_{max}\) in \(\rho_c(H)\), respectively. Since it is difficult to decide the onset of the oscillation, \(H_s\) was defined as \(\delta R_1 = 0\) by extrapolating \(R_{min,1}/R_{max}\) to 1, so that \(H_s\) may include more ambiguity than \(H_{1/2}\). The slope of the fitted line is slightly smaller than Eq. (2) with a factor of 0.68, meaning \(H_s = 1.2H_{tr}\). Below \(H_{tr}\), JV lattices incommensurate along the \(c\) axis are expected in the bulk as results of the sharing transitions from the triangular JV lattice. Considering the boundary effect which may suppress the sharing transition, the deviation could be reasonable. The result that \(H_{1/2}\) can be scaled by \(\gamma\) suggests that the crossover between \(\phi_0/2\) and \(\phi_0\) oscillations is a result of competition between bulk sharing energy and the edge boundary effect for JVs. The argument that the \(\phi_0\) oscillation is attributed to the Fiske step at higher bias current is not supported because \(dV/dI\) at \(I = 0\) shows almost same behavior as ohmic resistance \(V/I\), as shown in the inset of Fig. (1b). Therefore such a non-linear effect in voltage should not be considered in this current region.

\[(k + 1/2)\phi_0\text{. Such a Fraunhofer oscillation in } J_c(H) \text{ of multilayered system like Bi2212 is expected when condition } L \ll \lambda_f \equiv \gamma s \text{ is satisfied.} \]

\(\lambda_f\) is estimated to be approximately 0.2 \(\mu\)m for \(\gamma = 100 - 200\), which is much smaller than the \(L\) of these samples.

The experimental results demonstrate that the \(\phi_0\) oscillation is a phenomenon induced by the external magnetic fields, thus it is important to consider competition between the bulk and the boundary effects for JV’s. At relatively low fields where JV’s start to form dense triangular lattices, the JV positions are mostly determined by the sharing interaction between vortices in adjacent layers due to the inductive coupling between layers. With increasing magnetic field, vortices inside the layer become closer, and interaction between intra-layer JV’s is pronounced. The JV system is finally dominated by the surface deformation energy that lets JV’s align in phase and turns toward the square lattice in the high field region at the cost of sharing energy between JV arrays. Since the sharing energy of JV’s in a smaller junction with less JV’s is smaller while the surface deformation does not depend on \(L\), the \(\phi_0\) oscillation is observed at a lower field. The single-junction-like behaviors are more pronounced in samples with shorter \(L\) and at higher \(H\).
The temperature dependence of the crossover field is also consistent with the preceding discussions. As temperature is increased, $H_{1/2}$ considerably shifts to a lower field from 60 to 82 K as shown in Fig. 2. We derived $\gamma$ with Eq. 1 and plotted it in the inset of Fig. 2(b) as a function of temperature. It has been reported that $\gamma$ drastically increases in the vicinity of $T_c$. It was also found that the amplitude of the oscillation of both $\rho_c(H)$ and $I_0(H)$ is maximized at 60-70 K. This can be understood that the synchronization of stacked junctions is optimized at the temperatures: thermal fluctuation below 60 K smears the inhomogeneities contained in the crystal and helps form regular JV lattice, but thermal fluctuation above 70 K smears the matching conditions.

In summary, we investigated the Josephson vortex lattice structure in mesoscopic (~$\mu$m) IJJ’s with a probe of the JV flow resistance along the c axis. The c-axis resistivity $\rho_c$ oscillates as a function of applied magnetic field with an oscillation period changing from $\phi_0/2$ to $\phi_0$, which indicates triangular JV lattice and a possible square JV lattice, respectively. Crossover field $H_{1/2}$ linearly decreases with junction length $L$. This is attributed to the interplay between the boundary effect and the inductive coupling between JV arrays in IJJ’s.

Acknowledgments

We thank M. Machida and A. Koshelev for their fruitful discussions and critical comments. This work was partially supported by the Grant-in-Aids for Young Scientists (B) and the Core-to-Core Program “Nanoscience and Engineering in Superconductivity” by Japan Society for the Promotion of Science (JSPS).
