Bacteria in the soil compete for limited resources. One of the ways they might do this is by producing antibiotics, but the metabolic costs of antibiotics and their low concentrations have caused uncertainty about the ecological role of these products for the bacteria that produce them. Here, we examine the benefits of streptomycin production by the filamentous bacterium *Streptomyces griseus*. We first provide evidence that streptomycin production enables *S. griseus* to kill and invade the susceptible species, *S. coelicolor*, but not a streptomycin-resistant mutant of this species. Next, we show that the benefits of streptomycin production are density dependent, because production scales positively with cell number, and frequency dependent, with a threshold of invasion of *S. griseus* at around 1%. Finally, using serial transfer experiments where spatial structure is either maintained or destroyed, we show that spatial structure reduces the threshold frequency of invasion by more than 100-fold, indicating that antibiotic production can permit invasion from extreme rarity. Our results show that streptomycin is both an offensive and defensive weapon that facilitates invasion into occupied habitats and also protects against invasion by competitors. They also indicate that the benefits of antibiotic production rely on ecological interactions occurring at small local scales.

**KEY WORDS:** Antibiotics, microbial competition, spatial structure, *Streptomyces*, streptomycin.
Competition between *Escherichia coli* is of both historical and ecological relevance. This species during four days of pairwise competition. (B) Fitness of *Streptomyces*.

**Figure 1.** Competition between *S. griseus* and *S. coelicolor* mixed at equal frequencies. (A) Initial and final densities of *S. griseus* and a fully susceptible strain of *S. coelicolor* during four days of pairwise competition. (B) Fitness of *S. griseus* competed against susceptible *S. coelicolor* WT (MIC 2 µg/mL streptomycin), intermediate resistant (MIC 12, 24, or 48 µg/mL) or high-level resistant (MIC 192 µg/mL) *S. coelicolor* mutants. Error bars represent standard errors of the mean.

Although these results, together with other studies indicating an aggressive function for antibiotics, seem to favor the traditional view of antibiotics as weapons, there are few studies that directly quantify the fitness effects of antibiotic production or that clarify their role as either offensive or defensive weapons for interference competition (Wiener 1996, 2000; Abrudan et al. 2015). In contrast, the population dynamics mediated by bacteriocins, especially those of *Escherichia coli* colicins, have been studied extensively (reviewed in Riley and Gordon 1999). These antibacterial peptides/proteins generally have a narrow killing spectrum due to their mechanisms of recognition and transport, and therefore only inhibit the growth of closely related bacteria. Classic studies by Adams et al. (1979) and Chao and Levin (1981) found that the outcome of competition between a colicin producing and a sensitive strain was frequency dependent, with the toxin producer only gaining an advantage when relatively common. Underlying this frequency-dependent effect is the lower growth rate of the colicin producing strain, due in part to lysis required for secretion, and the killing of the sensitive strain by the colicin (Adams et al. 1979). However, in a structured habitat, the producing strain could invade even from rarity. Toxin release creates a zone of competitor-free space around the producer and thereby provides privileged access to nutrients, while in a nonstructured habitat the nutrients are equally distributed to both competitors (Chao and Levin 1981). Although antibiotics and bacteriocins are both antimicrobial toxins, their costs of production may be very different because bacteriocin secretion can require cell lysis, making it extremely costly. Whether similar invasion dynamics are observed with antibiotics, that do not require the death of the producer, is studied here.

To address these dynamics and to provide insight into the role of antibiotics, we chose to study the fitness effects and establishment conditions of antibiotic production in the filamentous soil-dwelling bacterial species *Streptomyces griseus*. *Streptomyces* are prolific producers of antibiotics, including more than half of the antibiotics used in clinical practice, as well as a diversity of other secondary metabolites with antifungal, antiparasite, or anticancer activities (Bérdy 2005; Hopwood 2007; Barka et al. 2016). *S. griseus* is of both historical and ecological relevance. This species produces streptomycin, a broad-spectrum aminoglycoside antibiotic, that inhibits translation and was the first clinically deployed antibiotic from *Streptomyces* to be discovered (Schatz et al. 1944; Pfuette et al. 1955). Streptomycin production in *S. griseus* is regulated by the secretion of a gamma-butyrolactone signal called A-factor. The growth-dependent accumulation of A-factor results, through the pathway-specific regulator strR, in the production of streptomycin as well as in the formation of aerial hyphae (Ohnishi et al. 1999; Bibb 2005; Horinouchi 2007). *S. griseus* is also biogeographically widespread, with significant variation in streptomycin resistance (Laskaris et al. 2010) and production (preliminary data) across natural isolates. By examining the population dynamics of competition experiments between *S. griseus* and a streptomycin-sensitive competitor, *S. coelicolor*, we provide clear evidence that streptomycin is an offensive weapon that facilitates invasion, while also showing that the capacity for invasion varies with population density and frequency and is significantly facilitated by spatial structure.

**Results**

**STREPTOMYCIN ENABLES S. GRISEUS TO INVADE S. COELICOLOR**

We first asked whether *S. griseus* could invade a population of streptomycin susceptible *S. coelicolor* (Minimal Inhibitory Concentration [MIC] 2 µg/mL) by growing the two species together in paired competition. Both competitors were mixed at equal densities and a total of 10^5 spores were plated and then, after growth, spores were harvested four days later. Importantly, when
grown alone under these conditions, *S. coelicolor* produces significantly more spores than *S. griseus* (Fig. S1, unpaired *t*-test, df = 4, \( P = 0.002 \)), leading to the null hypothesis that this species would be competitively dominant. However, when the two species were mixed in the ratio of 1:1, *S. griseus* readily displaced *S. coelicolor* (Fig. 1A), a result that is due to the decline of the susceptible species. We repeated this experiment using strains of *S. coelicolor* with decreased susceptibility to streptomycin (MIC ranging from 12 to 192 \( \mu \)g/mL) due to mutations in the genes *rsmG*, a 16S methyltransferase, or *rpsL*, a 30S ribosomal protein, that are known to confer streptomycin resistance (Shima et al. 1996; Nishimura et al. 2007; Westhoff et al. 2017). This revealed that the fitness of *S. griseus* declined in competition with streptomycin-resistant strains (Fig. 1B). These results provide direct evidence that streptomycin production, rather than any other secreted metabolites of *S. griseus*, allows this species to invade *S. coelicolor*. The data also suggest that *S. griseus* at these densities produces quite high concentrations of streptomycin, because only the strain of *S. coelicolor* with the highest MIC (192 \( \mu \)g/mL) was able to prevent *S. griseus* invasion.

**STREPTOMYCIN PRODUCTION INCREASES WITH INOCULATION DENSITY**

To estimate how much streptomycin *S. griseus* produces, we measured the size of inhibition zones against *S. coelicolor* and compared these to zones produced by known concentrations of purified streptomycin. We first generated a standard curve by excising agar plugs from plates made with increasing concentrations of streptomycin and then placing these on a plate inoculated with *S. coelicolor*. As expected, this revealed that halos became larger with increasing streptomycin concentrations for plates inoculated with the wild-type (WT) strain. For plates inoculated with strains with intermediate levels of resistance (MIC is equal to 12 and 24 \( \mu \)g/mL streptomycin), smaller halos appeared only at higher streptomycin concentrations and halos were absent in the strain with the highest MIC (192 \( \mu \)g/mL) (Fig. 2A). These results were used to estimate streptomycin production by excising agar plugs from four-day-old plates inoculated with different initial densities of *S. griseus* spores (Fig. 2B). As with pure streptomycin (Fig. 2A), we found that the size of the zone of inhibition increased for the susceptible strain of *S. coelicolor* but saturated at low densities of *S. griseus*, reaching a maximum halo size at an inoculum density of \(~ 10^3\) *S. griseus* spores. This indicates that even at low densities (in monoculture), *S. griseus* produces as much antibiotic as a pure streptomycin stock prepared at 128 \( \mu \)g/mL. As with the pure streptomycin, we observed smaller halo sizes when *S. griseus* plugs were placed on plates containing *S. coelicolor* strains with intermediate streptomycin resistance and no halos with the high-level resistant strain (Fig. 2B). These results show that streptomycin production occurs at high levels and is density dependent.

**CONDITIONS MODIFYING *S. GRISEUS* INVASION**

Having established that *S. griseus* produces high concentrations of streptomycin and that this enables *S. griseus* to outcompete *S. coelicolor* when the two strains are equally common, we next sought to identify conditions that influence the invasibility of this strain. We focused specifically on *S. griseus* density and frequency as we predicted that these would impact the ability for an antibiotic producing strain to invade when rare and on the role of spatial structure. The latter parameter has been shown to be particularly important for bacteriocin invasion by allowing producing strains to benefit locally from their own toxin production by creating competition-free space surrounding the producing colony (Chao and Levin 1981). Competition experiments in Fig. 3A clarify that the fitness of *S. griseus* is strongly density dependent (one-way analysis of variance [ANOVA], \( F_{3,8} = 58.62, P < 0.0001 \)) and that this species can invade from a minimum of \(~ 10^3\) spores/plate when competed against a *S. coelicolor* strain with a streptomycin MIC of 48 \( \mu \)g/mL. We can explain these results in two ways. First, less streptomycin is produced when there are fewer *S. griseus* cells
on the plate, thus leading to less inhibition of *S. coelicolor*. Second, when fewer spores are plated, the distance between colonies increases. This means that in the vicinity of a producer there are fewer susceptible colonies to inhibit, which reduces the benefit of producing the antibiotic. To distinguish between these two possibilities, we next varied the frequency of *S. griseus* in the population (Fig. 3B), while holding the initial density constant at $10^5$ spores per plate. This enabled us to vary the amount of streptomycin produced, while the average distance to neighboring *S. coelicolor* colonies remained constant. The results of these experiments reveal that the fitness benefits of antibiotic production by *S. griseus* are significantly frequency dependent (one-way ANOVA, $F_{2,15} = 71.39, P < 0.0001$) and increase with their relative frequency (Fig. 3B). However, these experiments also indicate that the threshold for invasion is relatively high, and that *S. griseus* needs to reach at least 1% of the population before it benefits from antibiotic production. This result raised the question of how *S. griseus* could reach a frequency of 1% from much lower initial values, or if there are conditions that could lower this threshold to permit invasion from fewer cells.

To address this issue, we set up experiments to determine the invasion threshold of *S. griseus* in conditions where spatial structure was either maintained over the course of eight serial passages, or was periodically destroyed. These experiments were in part motivated by our observations that we could observe very small inhibition zones surrounding *S. griseus* colonies when competing with *S. coelicolor*, even when *S. griseus* was at low frequencies (see Fig. 4A inset). Although these tiny inhibition zones were insufficient to provide short-term fitness benefits (Fig. 3B), we hypothesized that they might permit *S. griseus* to expand from these regions if local structure were maintained. At each transfer, we used replica plating to maintain the spatial structure in each replicate across time. To destroy spatial structure, we simply rotated the plate for the next transfer cycle onto the velvet used for replica plating (Kerr et al. 2002). Consistent with our predictions, we found that maintaining spatial structure enabled invasion from much lower frequencies. When retaining the spatial structure, *S. griseus* was able to invade from an initial frequency of as low as 0.001% and then become fixed in the population (Fig. 4A). Given the initial total inoculation density of $10^5$ spores, this indicates that no more than 10 spores are required for invasion. By contrast, when the spatial structure was destroyed at each transfer cycle, the threshold for invasion increased ~100-fold to 0.1% (Fig. 4B). The cause of these results is clearly illustrated in Fig. 4C (and more detailed in Fig. S2), showing that minute halos expand through time and then eventually coalesce when spatial structure is maintained, but that these halos disappear when it is destroyed. However, it is important to note that spatial structure is in itself insufficient to enable invasion, because when *S. griseus* is competed against a highly resistant strain of *S. coelicolor*, its invasion is prevented even though it was inoculated at a relatively high frequency (Fig. 4D). These results further support the conclusion that streptomycin production and sensitivity are the key factors driving the population dynamics of these two species.

**Discussion**

Antibiotic production by microbes is ubiquitous in nature, with streptomycin being one of the most commonly produced antibiotics; it has been estimated that 1% of randomly screened actinomycetes from around the globe can synthesize this antibiotic (Baltz 2008). Although this suggests that antibiotic production confers benefits, very little is known about the population dynamics of antibiotic production and the conditions that influence how antibiotic producers become established. Here, we focus on the importance of streptomycin for its producer *S. griseus* during competitive interactions with susceptible and resistant strains of
Figure 4. Changes in frequency of *S. griseus* in competition with streptomycin susceptible *S. coelicolor* WT when spatial structure is (A) maintained by replica plating or (B) destroyed by rotating the plate on the velvet used for replica plating in different directions. Inset in (A) shows a representative image of an inhibition zone around a *S. griseus* colony, scale bar 500 µm. (C) Representative images of plates from (A) and (B) at different initial *S. griseus* frequencies. (D) Frequency of *S. griseus* in competition with streptomycin susceptible or highly resistant *S. coelicolor* (MIC 192 µg/mL) when spatial structure is maintained.
**S. coelicolor.** Our results show that antibiotic production occurs at high levels and that this enables *S. griseus* to kill and therefore invade a population of drug-susceptible competitors. However, this only occurs if *S. griseus* is numerous and at fairly high frequencies, otherwise it fails to outcompete *S. coelicolor.*

These results support the classic studies of Chao and Levin (1981) and Greig and Travisano (2008) who showed that the fitness benefits of allelopathy are enhanced by spatial structure. Our results from short-term competition experiments closely mirror those seen for colicin production in *E. coli,* where in mass action environments, producing cells must be moderately common to benefit from colicin production. This leads to two alternative outcomes; colicin producers fix or they go extinct. As classically shown by Chao and Levin, the reason for this result is that the costs of colicin production, including cell lysis necessary for secretion, exceed the benefits of production in an environment with high rates of diffusion (Chao and Levin 1981). Although antibiotic secretion is not lethal in streptomycetes, it is expected to be metabolically expensive, with pathways for secondary metabolites comprising ~5% of Streptomyces genomes (Challis and Hopwood 2003; Nett et al. 2009). Streptomycin production requires the growth-dependent accumulation of A-factor, a small signaling molecule, which through the pathway-specific regulator strR results in the transcription of the streptomycin cluster, a 31 kb gene cluster consisting of 27 genes, as well as the formation of aerial hyphae (Distler et al. 1992; Bibb 2005; Ohnishi et al. 2008). Similarly to rare colicin producers, when *S. griseus* is rare, it produces insufficient streptomycin in the competition environment to invade, a result that may be partly due to a failure to activate streptomycin production via accumulated A-factor. Even though we were unable to detect a fitness benefit of streptomycin production under these conditions, we often observed extremely small zones of clearance around minute *S. griseus* colonies. This suggests the possibility that continued cultivation would allow *S. griseus* to thrive, as long as cells could directly benefit from their own antibiotic production. Serial transfer experiments where the spatial structure was either retained or periodically destroyed indeed revealed that spatial structure lowered the threshold of invasion by more than 100-fold to fewer than 10 total cells, in parallel with the classic results from Chao and Levin (1981).

The temporal dynamics of these experiments (Fig. 4C and Fig. S2) help to explain our results. Rare streptomycin producers secrete sufficient amounts of the antibiotic to create a small zone of inhibition, thereby freeing space and resources for their growth. With continued cultivation over several transfer cycles, these halos continue to expand radially as the size of the producing colony of *S. griseus* grows. Eventually, halos from separate colonies coalesce, leading to rapid fixation of the antibiotic-producing strain. Because the benefits of antibiotic production remain local, the costs of production can be overcome. However, when spatial structure is destroyed, these local benefits are diluted. Zones of inhibition never expand, because cell densities of founding colonies remain low, so the benefits of streptomycin production remain unchanged through time. By lowering the threshold required for invasion of antibiotic producers, spatial structure may provide more opportunities for the frequency-dependent invasion of antibiotic producing strains in mixed microbial communities (Wright and Vetsigian 2016).

Streptomycetes in soil live on soil grains where overall cell densities are anticipated to be heterogeneous and patchy (Probandt et al. 2018). One of the challenges to understanding the role of antibiotics in nature is that their estimated concentrations in bulk soil are extremely low. Aside from technological limitations that may contribute to these estimates, our results show that as long as competition remains local, low antibiotic concentrations in bulk soil are not informative of their potential benefits because producing cells can still inhibit and kill local competitors. Additionally, it has been shown that even if drug concentrations are low (up to 100-fold lower than the MIC), they are sufficient to rapidly select for antibiotic resistance (Gullberg et al. 2011; Westhoff et al. 2017). Thus, the coexistence, at small spatial scales, of bacterial strains that produce and are resistant to antibiotics is most consistent with the argument that antibiotics are used to mediate competitive interactions (Vetsigian et al. 2011).

It is important to note, however, that our experiments differ in many ways from the conditions bacteria face in nature. First, rates of diffusion and the availability of resources will markedly differ in highly heterogeneous soil compared to a homogeneous agar plate, where antibiotic diffusion is essentially unconstrained and resources are high. Second, while cells are uniformly distributed on our agar plates, they will be more patchily distributed in soil (Vos et al. 2013). Microscopic analysis of sand grains from marine sediments revealed that colonization is highly uneven, with protected areas on individual grains being more densely populated than exposed areas (Probandt et al., 2018). Because the fitness of *S. griseus* scales with density, the colonization density in nature will undoubtedly influence the benefits of antibiotic production. Both of these concerns could begin to be addressed by extending our experiments to soil microcosms to approximate the spatial structure provided by natural soils. Third, the model organisms used in this study were not isolated from the same soil sample, meaning they did not co-evolve. Because inhibitory interactions between *Streptomyces* strains from the same soil core are often reciprocal, with increased reciprocity between strains isolated from the same soil grain (Vetsigian et al. 2011), competitive interactions between coevolving strains in nature are likely to be more complex than the dynamics presented here. Finally, our experiments do not include longer term interactions that include the evolution of antibiotic resistance. It is possible that de
novel resistant strains would exclude antibiotic producers. However, under local competition, these strains could also facilitate the coexistence of antibiotic production, resistance, and susceptibility, as has been observed in the real-life rock-paper-scissor dynamics of colicins, both in vitro and in vivo (Kerr et al. 2002; Kirkup and Riley 2004). Considering these factors under more environmentally realistic conditions is an obvious and important next step in our work. To summarize, our results indicate that antibiotics can be used as offensive weapons to invade established populations of competitors from a low frequency and suggest that structured habitats are favorable for this invasion and thereby for the evolution of antibiotic producers. They also suggest that bulk-soil estimates of antibiotic concentrations may be misleading with respect to the role of these compounds in nature, and instead argue for the importance of estimating drug concentrations at small spatial scales that better reflect the competitive arena where these metabolites are used.

**Materials and Methods**

**STRAINS AND CULTURING CONDITIONS**

Two Streptomyces species were used in this study: the streptomycin-producing *S. griseus* IFO13350 (MIC 92 µg/mL) and the streptomycin-sensitive *S. coelicolor* A(3)2 M145 (MIC 2 µg/mL) carrying an integrated pSET152 plasmid conferring apramycin resistance. Spontaneous streptomycin-resistant mutants of *S. coelicolor* A(3)2 M145 described in Westhoff et al. (2017) were also used. Briefly, to obtain these mutants, spores were plated on antibiotic concentrations above the MIC and resistant colonies were picked after several days and tested for MIC. We selected low-level resistant (MIC 12, 24, and 48 µg/mL, respectively) and high-level resistant (MIC 192 µg/mL) strains for these experiments. The MIC was determined as the lowest concentration of streptomycin yielding no growth four days after spotting ~10⁴ spores on Soy Flour Mannitol Agar (SFM) with increasing concentrations of streptomycin. Strains were transformed with the integrating pSET152 plasmid conferring apramycin resistance for the competition experiments, which has no effect on fitness (Westhoff et al. 2017).

Strains were grown routinely for four days at 30°C on SFM containing 20 g soy flour (Biofresh Belgium, Onze-Lieve-Vrouwe-Waver, Belgium), 20 g mannitol (Merck KGaA, Damstadt, Germany), and 15 g agar (Hispanagar, Burgos, Spain) per liter (pH 7.2–7.4). High-density spore stocks were generated by uniformly spreading plates with 50 µL of spore containing solution. After several days of growth, spores were harvested with a cotton disc soaked in 3 mL 30% glycerol after which spores were extracted from the cotton by passing the liquid through an 18 g syringe to remove the vegetative mycelium. Spore stocks were titred and stored at −20°C.

**COMPETITION EXPERIMENTS**

We carried out competition experiments between *S. griseus* and the streptomycin susceptible WT or resistant mutants using streptomycin and apramycin resistance as markers. Competition experiments were initiated by mixing strains at the given frequencies and plating 50 µL containing 10⁵ spores unless otherwise indicated. To determine the fraction of our inoculum that was streptomycin or apramycin resistant, we simultaneously plated a dilution of this mix on SFM containing 40 µg/mL streptomycin sulfate (Sigma, St. Louis, MO, USA) or 50 µg/mL apramycin sulfate (Duchefa Biochemie, Haarlem, The Netherlands). After four days of growth, the plates were harvested and the number of each competitor quantified following plating on SFM with streptomycin or apramycin. Following Travisano and Lenski (1996), the selection rate (*r*) was calculated as the difference in the Malthusian parameters of both strains: $r = \ln[\text{S. griseus} (t = 4)/\text{S. griseus} (t = 0)] – \ln[\text{S. coelicolor} (t = 4)/\text{S. coelicolor} (t = 0)]$, where *t* is the time in days of growth after inoculation.

**QUANTIFYING STREPTOMYCIN PRODUCTION**

We developed a halo assay to quantify the production of streptomycin by *S. griseus*. We prepared plates with known concentrations of streptomycin and plates with varying inoculation densities of *S. griseus* spores and incubated these for four days at 30°C. We took 10 mm agar plugs from these plates using the back end of a sterile 1-mL pipette tip and removed the top 2 mm to remove the *S. griseus* mycelium. At an inoculation density of 10⁵ spores, the lowest density tested and growth consisted of single colonies. To ensure consistency with our measurements of inhibition, we always chose plugs containing a single colony, an approach that could overestimate the amount of streptomycin produced at this density. We incubated the plugs for three days on 50 µg/mL apramycin SFM plates (to prevent any residual *S. griseus* growth) inoculated with 10⁵ spores of streptomycin susceptible or resistant *S. coelicolor* before we measured the halo diameter.

**SERIAL TRANSFER EXPERIMENTS**

To determine the effect of spatial structure on invasion, *S. coelicolor* and *S. griseus* were mixed at the indicated frequencies and 10⁵ spores were plated and grown for four days. An imprint of this plate (resulting in transfer 0) was made on a velveteen cloth and two plates were replicated from this: (1) a plate was replicated in the same orientation to maintain the spatial orientation of the original plate; and (2) a plate was replicated by pressing the plate on the velveteen cloth in four different orientations by rotating the plate a quarter turn each time to destroy the spatial orientation. No streptomycin was transferred via the velvet (data not shown). From this point, plates continued to be replicated in the same manner after four days of growth for a total of four or eight transfers depending on the experiment. Before each transfer, the
plates were imaged using a flatbed scanner. After every transfer, the remaining spores on the plate were harvested and the ratio of *S. griseus* and *S. coelicolor* was quantified following plating on SFM with streptomycin or apramycin.

**AUTHOR CONTRIBUTIONS**

SW, SBO, and DER designed the experiments; SBO, AS, BB, and SW performed the experiments; and SW, DER, and GPvW wrote the manuscript.

**ACKNOWLEDGMENTS**
