Plouvier S, Leclerc A, Chastang J-F, Bonenfant S, Goldberg M. Socioeconomic position and low-back pain – the role of biomechanical strains and psychosocial work factors in the GAZEL cohort. Scand J Work Environ Health. 2009;35(6):429–436.

Objective To analyze the role that biomechanical strains and psychosocial work factors play in occupational class disparities in low-back pain in the GAZEL cohort.

Methods Recruited in 1989, the GAZEL cohort members were employees of the French national company in charge of energy who volunteered to enroll in an annual follow-up survey. The study population comprised 1487 men who completed questionnaires in 1996 (past occupational exposure to manual material handling, bending/twisting, and driving), 1997 (psychosocial work factors), and 2001 (low-back pain using a French version of the Nordic questionnaire for the assessment of low-back pain). Associations between low-back pain for >30 days in the preceding 12 months and social position at baseline (four categories) were described with a Cox model to determine prevalence ratios for each category. We compared adjusted and unadjusted ratios to quantify the contribution of occupational exposures.

Results The prevalence of low-back pain for >30 days was 13.6%. The prevalence of low-back pain adjusted for age was significantly higher for blue-collar workers and clerks than for managers. The number of socioeconomic disparities observed was significantly reduced when biomechanical strains were taken into account; adjusting for psychosocial factors had little impact.

Conclusion In this population, occupational exposures – especially biomechanical strains – played an important role in occupational class disparities for persistent or recurrent low-back pain.

Key terms health inequality; musculoskeletal disorder; occupational exposure; social inequality; socioeconomic status.

For most health dimensions, health status is worse in lower socioeconomic groups. Such socioeconomic disparities have been described for back pain in several studies (1–4). Many factors vary between groups according to socioeconomic position and may thus contribute to social inequalities in health; these can include early life circumstances, lifestyle, the physical and psychosocial environment, employment, and working conditions (5, 6). Some occupational factors contribute to the association between socioeconomic position and self-rated health in cross-sectional studies (7–13), and the social gradient in the deterioration in self-rated health over one year (12) and five years (14). Other studies have looked at the contribution of working conditions to social inequalities in depressive symptoms, physical functioning (15), longstanding illness (11), and the incidence of coronary heart disease (16) for instance.

A few studies have indicated that occupational factors contribute to socioeconomic disparities in musculoskeletal disorders in general (8, 17–19). Physical and psychosocial work characteristics accounted for a substantial part of the relation between socioeconomic status and musculoskeletal complaints in men who graduated from high school in Wisconsin (8). Physical demand at work explained a large part of occupational class disparities in musculoskeletal disorders for employees of the city of Helsinki (17). In a study of a working population in France (the Pays de la Loire study), physical occupational factors accounted for more than 50% of the disparities between manual and professional and administrative categories (18). The association between socioeconomic position and low-back pain in the GAZEL cohort may be attenuated when occupational factors are taken into account.
Socioeconomic position and low-back pain

Non-manual workers for upper-limb disorders (18). In the general working population of Oslo, physical job demands and job autonomy explained a substantial portion of occupational class disparities in musculoskeletal complaints (19).

Physical exposures at work (e.g., bending, twisting, manual material handling, and whole body vibrations) are considered to be risk factors for low-back pain (20, 21); psychosocial factors at work are also reported to play a role (22, 23). These types of factors might, therefore, explain at least a part of the social inequalities in low-back pain. This question has not been examined in detail, and conclusions from the studies on this topic appear somewhat conflicting. In Oslo, working exposures, especially physical job demands, accounted for a substantial portion of the absolute inequalities between occupational classes for low-back pain (19). In a population-based survey in France, the association between education and low-back pain was also mainly mediated by physical factors at work (24), while a study in Germany was unable to explain the relation between education and severe back pain by occupational factors (25).

Our hypothesis in this study was that low-back pain is associated with socioeconomic position, and occupational exposures are a pathway for this relation. More precisely, we sought to assess the relations between low-back pain in the longitudinal GAZEL cohort and socioeconomic position (measured by occupational category or class), and analyze the contribution of biomechanical strains and psychosocial work factors to these relations.

Materials and methods

Population and study design

The GAZEL cohort was established in 1989. Its members were recruited among the employees of Electricité de France-Gaz de France, the French national company for the production and distribution of energy (26, 27). At that time, the company employed approximately 150 000 people of diversified trades and socioeconomic categories, with civil servant-like status throughout France. At baseline in 1989, the cohort included 20 624 volunteers, men then aged 40–50 years and women 35–50 years. In January of each year, participants receive a general questionnaire about their lifestyle, health, and occupational situation. Specific themes, such as low-back pain, are also explored.

The population for our study came from the population selected for the “GAZEL low-back pain” sub-project (28), which included 4 018 cohort members, 3 377 of whom were men. These members were randomly selected from occupational groups in which at least 20% of workers were exposed to selected occupational strains related to postures, vibrations, manual material handling, and video display terminals. This sample received specific questionnaires on low-back pain in 1992, 1994, and 1996. Our study population comprised the men who completed the 1996 low-back pain questionnaire, the 1996 and 2001 general questionnaires (N=2218), and the 1997 questionnaire on psychosocial factors at work. We therefore analyzed 1487 men (44%).

We analyzed information on: (i) socioeconomic position recorded in 1989, (ii) personal data and occupational history assessed in 1996, (iii) psychosocial factors at work compiled in 1997, and (iv) low-back pain self-assessed in 2001 (figure 1).

Socioeconomic position

Data on socioeconomic position at baseline (1989) were extracted from corporate files and coded according to the French national classification of occupations and socioeconomic categories (PCS). Four categories were used: (i) managers and higher intellectual professions, (ii) intermediate professions (e.g., technicians, foremen, supervisors, teachers), (iii) clerks, and (iv) blue-collar workers.

Low-back pain

The 2001 general questionnaire collected information about low-back pain with questions derived from the Nordic questionnaire for the analysis of musculoskeletal...
symptoms (29). Low-back pain was defined by reference to a diagram of the body: “pain, discomfort or disability in this area, whether or not the pain radiates to the leg”. Subjects reported the cumulative duration of low-back pain during the previous 12 months (ie, 0 days, ≤7 days, 8–30 days, >30 days but not every day, or every day). The outcome of interest in the study was low-back pain that lasted >30 days, which is generally considered to be frequent or long-lasting pain (30).

Biomechanical strains
In the 1996 specific questionnaire, cohort members reported their cumulative duration of exposure during their working life to three biomechanical strains: (i) driving a car for >2 hours/day; (ii) usually pushing, pulling, or carrying heavy loads (at least once a week); and (iii) bending (forward/backward) or twisting repeatedly, daily or almost daily. Four answers were possible for each exposure (ie, never, <10 years, 10–20 years, >20 years).

Psychosocial factors at work
In the general 1997 questionnaire, psychosocial factors at work were assessed with a French version of the Karasek Job Content Questionnaire (31, 32). Respondents had to state the extent to which they agreed with each item (ie, completely agree, agree, do not agree, do not agree at all); a score was calculated for each of the three dimensions: (i) psychological demand (9 items), (ii) decision latitude (9 items), and (iii) social support received from coworkers and superiors (8 items).

Analyses
Relations between low-back pain in 2001 and socioeconomic position in 1989 were first assessed with Chi-square tests. We also verified that the occupational exposures studied were distributed differently across socioeconomic groups.

Thereafter, we used Cox regression models with a constant risk period (one year) assigned to everyone to obtain a prevalence ratio (PR) of low-back pain for each socioeconomic group compared with managers. Cox models were preferred to logistic regression models, because PR are easier to interpret than odds ratios, especially for rather common diseases (33). Robust variance estimates were used to calculate the confidence intervals (34).

In accordance with previous analyses, the duration of exposure was considered a quantitative variable (35). Each potential answer in the questionnaire, proposed as a category, was replaced by the value of its class center (ie, never=0, <10 years=5, 10–20 years=15, and >20 years=25). For each psychosocial scale, scores were dichotomized at the median of their distribution in the population. Age (in 1996) was forced into the models.

In a first set of analyses, we constructed age-adjusted models to study the associations between low-back pain and socioeconomic position, and between low-back pain and each occupational exposure, separately. Only the occupational factors associated with low-back pain at P-value <0.20 were kept for the subsequent models (models A, B, and C). In the initial model (model A), the age-adjusted association between low-back pain and socioeconomic position was further adjusted for the relevant biomechanical strains. In the second model (model B), the age-adjusted association between low-back pain and socioeconomic position was further adjusted for the relevant psychosocial factors. In the final model (model C), the age-adjusted association between low-back pain and socioeconomic position was adjusted for both the relevant biomechanical and psychosocial factors (those included in model A or B).

In each of these three models, we estimated the contribution of the occupational factors in the model (biomechanical strains, psychosocial factors, or both) to the association between low-back pain and socioeconomic position by comparing the PR of low-back pain for a defined socioeconomic position (adjusted and not adjusted for these factors) as follows (36, 37):

\[
\frac{(PR \text{ partly adjusted} - PR \text{ further adjusted for the factors added in the model})}{(PR \text{ partly adjusted} - 1)}
\]

We calculated confidence intervals for the contribution of occupational factors by bootstrap (38).

Results
Low-back pain and socioeconomic position
Intermediate grade was the most common socioeconomic position; there were few clerks among these male cohort members. The one-year prevalence of low-back pain for >30 days was 13.6% in the overall study population (table 1). A gradient in the prevalence of low-back pain was observed, with the smallest prevalence for the highest socioeconomic position (P-value for trend <0.0001). However, prevalence was rather similar in the two first categories, namely, managers and intermediate professions.

Socioeconomic position and occupational strains
Durations of exposure to biomechanical strains (given only for ≥10 years in table 1) varied according to socioeconomic position. Globally, the higher the socioeconomic position, the higher the percentage of
Low-back pain and occupational strains

The one-year prevalence of low-back pain increased with the cumulative duration of exposure to each biomechanical strain. It was also always highest for those exposed to a more strenuous level of psychosocial factors at work.

Low-back pain, socioeconomic position, and occupational strains

The first set of analyses with Cox models, adjusted for age, showed a significantly higher prevalence of low-back pain for blue-collar workers and clerks compared with managers (table 2). Low-back pain was significantly associated with each biomechanical strain and a low level of decision latitude. The association with a low level of social support was on the borderline of significance.

When the association between low-back pain and socioeconomic position was also adjusted for biomechanical strains (model A), the PR for blue-collar workers decreased by 73% and was no longer significantly different from 1. For clerks, it decreased by 45%, but prevalence for clerks remained significantly higher than that of managers.

When the age-adjusted association between low-back pain and socioeconomic position was also adjusted for the relevant psychosocial factors – decision latitude and social support (model B) – the PR for blue-collar workers and clerks decreased by 11% but remained significantly different from 1.

Finally, in the fully adjusted model (model C), the PR for blue-collar workers decreased by 77%, compared with the age-adjusted model, and by 74% when compared with the model adjusted for age and psychosocial factors. For clerks, the corresponding figures were 51% and 44%, respectively. Therefore, the risk of low-back pain for these two categories compared with managers was no longer significantly increased.

Most confidence intervals for the percentages of change, given by bootstrap, were large. However, the lower limits of the confidence intervals for percentages of change associated with adjustment on biomechanical strains were ≥0.25 (depending on the models compared) for blue-collar workers. For clerks, the corresponding values were >0.12. The confidence intervals suggested that taking into account decision latitude and social support did not change significantly the PR.

Discussion

This study, based on a longitudinal design, showed occupational class disparities for persistent or recurrent low-back pain among men in the GAZEL cohort. Occupational strains played an important role in these inequalities. Physical factors accounted for the greatest portion of the observed disparities, even when the role of psychosocial factors was also taken into account.

Before discussing these results, some limitations of the study must be considered. First, we could not study the relations between low-back pain and socioeconomic position among women because there were not enough of them in the GAZEL cohort. Therefore only men could be included.

The final response rate was rather low, especially because only 67% of the men who completed the 1996

*Adjusted for age.
*Prevalence ratios adjusted for age are issued from seven separated models, each one corresponding to one of the following variables: socioeconomic status (in four categories); driving (quantitative); bending/twisting (quantitative); handling loads (quantitative); psychological demand (two categories); decision latitude (two categories); social support (two categories).
*Model A: Relations between low-back pain and socioeconomic status, adjusted for age and biomechanical strains.
*Model B: Relations between low-back pain and socioeconomic status, adjusted for age, decision latitude, and social support.
*Model C: Relations between low-back pain and socioeconomic status, adjusted for age, biomechanical strains, decision latitude, and social support. Prevalence ratio given for 20 years of exposure.

and 2001 questionnaires responded to Karasek’s Job Content Questionnaire in 1997. Most of those who did not complete this questionnaire had already retired in 1997 and thus did not answer the questions on psychosocial factors at work. The legal age for retirement is rather low in France; in addition, those who held specific jobs classified as strenuous in Electricité de France-Gaz de France were allowed to retire before the legal age for retirement. Some subjects were also excluded because they answered only some questions. We chose not to use any method to substitute missing answers so that we could have a “straight” evaluation of psychosocial factors and optimize our assessment of their contribution to the relations of interest.

A validated self-administered questionnaire was used to assess these psychosocial factors (32). Physical exposure was also self-assessed in this study (39). Moreover, the assessment was retrospective, as it concerned the cumulative duration of exposure to biomechanical strains throughout the subjects’ working lives. Respondents’ answers appeared consistent with information they reported in earlier questionnaires. Nonetheless, we cannot rule out the possibility of recall bias. If such bias was present, it should not have been differential, since the information on low-back pain was collected five years later, in 2001.

The classification of socioeconomic position into four main categories was based on objective information provided by the company in 1989 and not self-assessment. However, as information on low-back pain and exposure at work were self-reported we cannot rule out the possibility of biases related to negative affectivity (19). Nevertheless, we expect them to be minimal, as information was collected at different points in time.

We chose to consider a definition of low-back pain independent of care seeking or sick leave, both of which are consequences that could be related, per se, to the occupational exposures studied. By selecting only disorders that lasted >30 days, we focused on low-back pain associated with high social and economic costs.

The data and the study design appeared appropriate for the discussion of hypotheses concerning “pathways” for inequalities in low-back pain. As low-back pain is rather common, statistical analyses based on Cox models were preferred to the computation of odd ratios (33).

The results suggest that occupational factors play an
important role in occupational class disparities in low-back pain. Other factors might have played a role. Obesity is more prevalent in lower socioeconomic classes and also a risk factor for low-back pain. Smoking has been associated with low-back pain in some studies and is also more prevalent in less-favored socioeconomic situations. In our population, smoking was not associated with low-back pain, and taking the body mass index into account did not change the contribution of occupational factors to the relation studied.

Psychosocial factors at work played a modest role in the relation between low-back pain and socioeconomic position. Each psychosocial dimension was studied separately, but we verified that combining these dimensions did not change our findings. Most of the study population had retired by 2001 and, thus, were no longer exposed to these working conditions. One explanation for the limited role of psychosocial factors in our results may be that the effects of these factors do not persist several years after exposure has ceased. We nonetheless noted that, in the literature, evidence is limited for the specific role of these factors in low-back pain; conflicting results are observed and some studies suffer from methodological shortcomings (22, 23). The modest role found for psychosocial factors at work in our study is, therefore, consistent with this literature.

Physical exposures at work played the greatest role in the relation between low-back pain and socioeconomic position. The contribution of these factors could also be analyzed for all the men for whom information on these exposures was available (the 2218 who completed the 1996 and 2001 questionnaires, irrespective of their participation in the 1997 questionnaire on psychosocial factors). Very similar results were observed for the relation between low-back pain, socioeconomic position and biomechanical factors at work, which validated our findings on biomechanical strains.

It might appear surprising that biomechanical strains had such an important role in explaining the excess risk of low-back pain among clerks in this population. This may be related to the fact that some of these clerks have also been blue-collar workers at some point in time; male clerks in Electricité de France-Gaz de France comprise workers with disabilities, no longer able to perform physically demanding tasks. Confidence intervals for percentages of change in PR show that the results for this group are imprecise, due to the small size of the group.

Generally speaking, confidence intervals for PR changes were wide. In most similar studies, these confidence intervals are not given, mainly because there is no standard statistical procedure for their calculation. It is probable that these confidence intervals are often large, especially if the samples are of limited size. The formula for PR change suggests also that this quantity could be imprecise if the denominator is ≈0, which is the case if the partly adjusted PR is ≈1. Despite a lack of precision, in this population, biomechanical strains explained a substantial part of the observed socioeconomic inequalities. The results based on the comparison between models C and B can be considered as the best measure, since they estimate the contribution of biomechanical strains in addition to psychosocial factors. However, these results were rather similar to those comparing models C and A.

For a better understanding of potential mechanisms leading to social inequalities in health, models are increasingly being compared (36). However, questions about causal mechanisms behind social inequalities are complex, and methods must also take into account knowledge from other fields of epidemiology.

Studies dealing with the contribution of occupational factors to socioeconomic disparities in low-back pain are scarce. The population we studied here could be considered specific, since it came from a single company with a civil servant-like status. Our results appear, nonetheless, consistent with those collected from other populations. For example, results on the same topic from the general population in France are in agreement with our findings (24); occupational disparities for low-back pain experienced by working people in Oslo were also found to be substantially mediated by working conditions and mainly physical demand (19).

Concluding remarks

In this study, biomechanical factors mainly accounted for socioeconomic disparities in persistent or recurrent low-back pain. Our findings showed that reducing occupational strains, particularly biomechanical ones, could substantially help to reduce socioeconomic disparities in persistent or recurrent low-back pain, mainly for blue-collar workers.
