INTRODUCTION

Incomplete regression of the mammary ridges may result in aberrant breast tissue, which can be classified based on its components [1]. Among the various types of breast choristoma, ectopic breast tissue, which has only glandular tissue without a nipple or areola, is most commonly detected in axillary areas. However, ectopic breast cancer is often not detected until significant clinical symptoms have been revealed, or diagnosis is delayed. Furthermore, an examination of ectopic breast tissue tends to be omitted from a screening mammography. Especially, the microcalcifications of ectopic breast tissue are difficult to delineate on mammography. Herein, the authors report a case of ectopic breast carcinoma that showed clustered microcalcifications on screening mammography, and discuss the interpretation and implications of microcalcification in ectopic breast tissue.

Key Words: Breast, Calcification, Choristoma

CASE REPORT

A 52-year-old woman with bilateral accessory breast tissue attended a local breast clinic for annual mammography and ultrasonography screening, during which clustered microcalcifications were detected in axillary regions [6-8]. The patient was then admitted to the clinic with a palpable axillary mass. An examination of the axillary region revealed a hard, fixed mass, and an irregularly shaped mass including microcalcifications was identified on mammography. A breast surgeon performed an excision biopsy of the axillary mass, and histologic observations revealed that the mammary ducts, within the fibrofatty stroma, were filled with and distended by microcalcifications.
a solid epithelial proliferation. The lesion measured 1.5 cm in the largest dimension. Necrosis and multifocal microcalcification were noted (Figure 2A), and the epithelial cells showed a moderate to high degree of nuclear atypia (Figure 2B). The patient was diagnosed as having high-grade ductal carcinoma in situ and was referred to our department for additional procedures.

Preoperative evaluation via positron emission tomography and computed tomography did not reveal any metastatic lesions. The patient underwent a wide local excision of the axillary ectopic breast tissue with a safety margin around the cavity of 1 cm; sampling of sentinel lymph nodes was also performed. For the evaluation of sentinel lymph nodes, 2 mL of a blue dye (indigo carmine) was injected into the peritumoral site. The weight of the excised ectopic breast tissue was 60 g; the contained microcalcifications were identified on specimen mammography.

In a section of the excised specimen, a cavitory lesion was noted along with focal fat necrosis due to the excision procedure. Remnant tumor was not clearly detected on macroscopic examination, but on microscopic examination, remnant tumor measuring 0.5 cm in maximum diameter was observed around the

Figure 1. Mammographic findings of ectopic breast cancer. (A) Aberrant breast tissue with clustered microcalcifications (dot circle) is detected on right axilla. (B) Magnified mammographic image of ectopic breast tissue with microcalcifications. A clustered microcalcification is well observed on ectopic breast tissue. (C) Mammographic findings of removed breast tissue. Multifocal microcalcification is apparent in two separately removed ectopic breast tissue specimens.
the cavity; histologic findings were similar to those for the excision biopsy. And there was no indication of metastasis to the lymph nodes among seven sentinel lymph nodes biopsied. Immunohistochemical assay showed positive and negative staining for the estrogen and progesterone receptors, respectively, and strong positive staining confirmed overexpression of the c-erbB-2 protein. Tamoxifen was administrated as adjuvant hormonal therapy. The patient continues to undergo surveillance up to 3 months after surgery, with no specific problems.

DISCUSSION

Ectopic breast tissue, a choristoma of the breast, can occur anywhere along the mammary ridge, and almost every form of breast disease can occur in ectopic breast tissue. Primary breast carcinoma arising from accessory breast tissue has been reported in 60% to 70% of all forms of ectopic breast tumor [2,9]. And the invasive ductal carcinoma is the most frequent histologic variant of primary ectopic cancer [10,11]. However, ectopic breast cancer is not easily detected because of the late expression of pathologic symptoms, and is commonly misdiagnosed as axillary lymph node disease, lipoma, or a sebaceous cyst [12]. Furthermore, we report a microcalcification in the axillary region, revealed on mammography; such findings could lead to ectopic breast cancer being overlooked or misdiagnosed as a calcification of the axillary lymph nodes. As late detection of ectopic breast cancer may lead to a worse prognosis, a precancerous sign or symptom should not be ignored. We wish to report the present case because of its rarity, as well as to highlight the implications of microcalcifications being discovered during the regular surveillance of ectopic breast tissue when an abnormality is detected on imaging.

When an abnormal image or symptom of ectopic breast tissue is noted, it should be evaluated in the same manner as for eutopic breast tissue. If a palpable mass is detected in ectopic breast tissue, a needle biopsy can be helpful for a differential diagnosis. If a malignant microcalcification is detected on mammographic imaging of aberrant breast tissue, it should be evaluated as to whether the calcification is located in a choristoma of the breast or a lymph node; a biopsy should be performed for further evaluation.

A malignant microcalcification on mammography strongly correlates with ductal carcinoma \textit{in situ} or invasive cancer [2,4,5]. When a malignant microcalcification is detected on mammography, a needle biopsy or excision biopsy should be performed to enable a correct diagnosis. This principle would also apply to ectopic breast tissue, because the components of such tissue are the same as those of an anatomically normal breast [2].

When ectopic breast cancer has been diagnosed, it is classified according to the TNM staging system used for primary breast carcinoma [13]. There is a clear distinction between ectopic breast cancer and occult breast cancer that presents in axillary lymph nodes; this is the reason for a thorough examination to accurately establish the location of a microcalcification. Ectopic breast cancer should be managed based on the treatment protocols for primary breast cancer, in contrast to the management of occult breast cancer. Although Francone et al. [3] strongly recommended the preventive excision of ectopic mammary tissue, the incidence of ectopic breast cancer is only 0.2% to 0.6% of all breast cancers, whereas the incidence
of postoperative complications (e.g., severe scarring, infection in the remaining sweat glands, pain, or discomfort) is reported to be as high as 4% to 10% [14,15]. However, preventive removal of ectopic breast tissue should be performed in cases that show abnormal signs or symptoms; if it were not performed, routine screening would be sufficient. A wide and complete resection of ectopic breast tissue is indicated after ectopic breast cancer has been diagnosed, and an evaluation of axillary lymph nodes is certainly indicated if the ectopic breast cancer occurs in the axillary region. Ectopic breast cancer can spread to the axillary lymph nodes more rapidly than a typical breast cancer [13]. Based on the TNM staging and characteristics of an ectopic breast cancer, adjuvant chemotherapy or radiotherapy can be administered, and hormonal therapy or targeted therapy can also be used, in accordance with the status of the relevant biological markers.

Although ectopic breast cancer is very rare, diagnostic modalities are usually the same as for typical breast cancer. However, it is not easily detected if a significant clinical symptom is not obvious, which may result in a delayed diagnosis and poor prognosis. A patient with aberrant breast tissue should be carefully evaluated with regard to both eutopic and ectopic tissue. When an abnormal finding is detected, such as clustered microcalcifications on mammography or a clinically palpable mass in ectopic breast tissue, a thorough evaluation should be undertaken.

Despite its rarity, symptomatic ectopic breast cancer is relatively easy to diagnose because of its similarity to typical breast cancer. However, it is less easily delineated on diagnostic imaging, leading to a late diagnosis and poor prognosis. Examination of accessory or ectopic breast tissue in affected patients should take place at the same time as the evaluation of eutopic breast tissue. Suspicious lesions, including microcalcification, should be followed up with close surveillance.
