Abstract

The ball sports-induced targetoid erythema (SITE) sign is a term that refers to annular erythematous lesions surrounding normal skin that occur after ball to skin contact. Associated purpura may be present or absent. A 19-year-old college student presented with multiple purpuric lesions of targetoid appearance. Additional history revealed that the lesions corresponded with the areas of ball contact during a paintball game. Similar lesions have been described in the participants of other sports, including floorball, ping pong, racquetball, and squash. When evaluating a patient with targetoid erythema with or without accompanying purpura, additional history of recent participation is an activity involving a high-velocity ball may be useful for establishing the diagnosis of the ball SITE sign.

Categories: Dermatology, Medical Simulation
Keywords: ball, ecchymoses, erythema, paint, paintball, purpura, sign, sports, targetoid

Introduction

Dermatoses may be associated with ball sports. One condition that has been observed is the ball sports-induced targetoid erythema (SITE) sign. The lesion may occur in participants of sports in which the size of the ball is usually small and the velocity is high [1].

The ball SITE sign was previously described as sports purpura [2]. However, this is a misnomer since the lesions can also be ecchymotic or both purpuric and ecchymotic [1]. A man who developed several purpuric targetoid lesions following contact from paintballs with his skin is described, and the features of the ball SITE sign are reviewed.

Case Presentation

A 19-year-old college student presented for evaluation of multiple asymptomatic red, skin lesions. Cutaneous examination showed three purpuric lesions that had a targetoid appearance of ecchymosis with normal-appearing skin in the center on his left scapula, left anterior shoulder, and left chest (Figure 1).
FIGURE 1: Paintball-associated ball sports-induced targetoid erythema (SITE) sign presenting as annular erythema on the left scapula, the left shoulder, and the left anterior chest.

Distant (a) and closer (b) views of the left scapula of a 14-year-old man show annular ecchymosis at the site of contact with a paintball (black arrows) three days earlier. The left shoulder (c) and left anterior chest (d) also show annular ecchymosis at the site of contact with a paintball (black arrows) that occurred three days earlier.

Additional history revealed that the patient had participated in a paintball activity three days earlier. The location of his cutaneous lesions corresponded to the sites where the paintball had contacted his skin. Correlation of the history and clinical presentation established the diagnosis of paintball-associated ball SITE sign.

Follow-up examination one week later (which was 10 days after the causative event) showed partial spontaneous resolution of the purpuric lesions on the left scapula and left anterior shoulder. The left chest lesion had completely resolved.

Discussion

The ball SITE sign has been associated with various sports (Table 1) [1-10]. The features of the
balls that can cause ball SITE sign vary. The composition can be gelatin (paintball), plastic (ping pong ball), or rubber (racquetball and squash ball) [1].

| Sport          | Reference |
|----------------|-----------|
| Floorball      | [1-3]     |
| Paintball      | [4-8]     |
| Ping pong      | [9]       |
| Racquetball    | [1,8,10]  |
| Squash         | [1,8,10]  |

**TABLE 1: Sports associated with the ball sports-induced targetoid erythema (SITE) sign**

aNomenclature of floorball-associated ball SITE sign includes floorball ecchymotic patches and floorball purpura.

bNomenclature of paintball-associated ball SITE sign includes paintball purpura, paint pellet erythema, and paint pellet purpura.

cNomenclature of ping pong-associated ball SITE sign includes ping pong patches.

dNomenclature of racquetball-associated ball SITE sign includes annular erythematous (and occasionally purpuric) patches, annular lesion, and racquetball-associated targetoid erythema (RATE) sign.

eNomenclature of squash-associated ball SITE sign includes annular erythematous (and occasionally purpuric) patches, annular lesion, and targetoid erythema associated with squash (TEAS) sign.

The weight of the ball can be as low as 2.5 grams for ping pong balls and as high as 58.5 grams for racquetballs. The weight for squash balls can be as high as 25 grams. In contrast, paintballs weigh approximately 3.5 grams [1,5,6,9,11].

The diameters of the balls also vary. Racquetballs, squash balls, and ping pong balls all have greater diameters of approximately 57 millimeters, 40 millimeters, and 39 millimeters, respectively. In contrast, the paintball has a much smaller diameter of only 17 millimeters [1,5,6,9,11].

The speed of the ball is usually fast. Paintballs have been observed to travel at 191 to 205 miles per hour. In contrast, the other balls travel slower than the paintballs. Ping pong balls travel at 100 miles per hour, whereas racquetballs (traveling 77 to 191 miles per hour) and squash balls (traveling greater than 150 miles per hour) often move faster [1,5,6,9,11].

Our patient developed the ball SITE sign following contact with his skin from paintballs. The ball SITE sign occurring in participants receiving skin impact from paintballs has been described previously (Table 2) [4-8].
Siegel et al., 1980

First report of a patient with paint pellet purpura. A 32-year-old woman had two lesions measuring 8-10 cm with ecchymotic margins and clear centers on her arm and back. These were the sites where she was hit by paint bullets during a survival game two days prior to her office visit.

### TABLE 2: Clinical characteristics of patients with paintball-associated ball sports-induced targeted erythema (SITE) sign.

CR, case report; pub, publication; ref, references; SITE, sports-induced targetoid erythema.

What is now referred to as paintball purpura was initially described as paint pellet purpura by Siegel in 1986 [8]. Subsequently, ball SITE sign associated with paintballs has been described as paintball purpura and paint pellet erythema. The patients ranged in age from 14 to 32 years [4-8]. The morphology of their lesions was either erythema, purpura, or both [4-8].

The differential diagnosis of ball SITE sign is described in Table 3 [12-16]. Although there are several clinical lesions that can mimic the morphology of the ball SITE sign, the associated history of trauma to the skin site from a high-velocity ball is helpful in establishing the diagnosis. Therefore, a biopsy is usually not necessary to confirm the diagnosis of the ball SITE sign.
The treatment of paintball purpura is symptomatic. They lesions typically resolve spontaneously as they did in our patient. Also, they often reoccur on new sites of skin contact when the individual again participates in the activity.

**Conclusions**

The term ball SITE sign was introduced to characterize lesions of targetoid erythema that present after high-velocity contact of ball to skin; these lesions occur in the setting of various sports, including paintball, ping pong, racquetball, and squash. The annular red ring of erythema may or may not concurrently present with purpura; our patient’s lesions had purpura. Also, similar to our patient, the lesions typically resolve spontaneously; therefore, a proper history is necessary to establish the diagnosis and avoid additional evaluation or unnecessary treatment.
