1. Introduction

Increasing demand for reduced automotive body weight and improved collision safety have greatly encouraged active use of high tensile strength steel sheets.1) These sheets have also been galvanized or galvannealed to achieve excellent anti-corrosion properties.

The steel sheets used in the automotive body structure can be divided into cold-rolled steel sheets, which are mainly used for outer/inner panels, and hot-rolled steel sheets, which are mainly used in underbody parts. Recently, galvanized high tensile strength hot-rolled steel sheets have been demanded by many automakers for weight reduction of underbody parts.2) Since addition of Si and Mn is a valid way to achieve the required mechanical properties, a galvanizing method which is applicable to Si, Mn-added hot-rolled steel is highly demanded.3–5) And most studies focused on the effect of the surface condition of hot-rolled steel which did not contain Si and Mn.14–27) Moreover, a small number of studies have investigated the effect of surface roughness and residual scale on the galvanizability of Si-containing hot-rolled steel, but the factors that inhibit galvanizability remain to be clarified.28,29)

In addition, because hot-rolled steel has less rolling strain than cold-rolled steel, it is not necessary to anneal hot-rolled steel over the recrystallization temperature. This means that production is possible at a low annealing temperature at which selective oxidation of Si and Mn are considered to be suppressed. Therefore, the main focus of this study is the galvanizability and selective oxidation behavior of Si, Mn-added hot-rolled steel when annealed at low temperature.

2. Experimental

Hot-rolled steel sheets containing 0.7 mass% Si-1.15 mass% Mn were used in the present study. The sheet thickness was 2.3 mm, and the chemical composition of the steel sheets was as shown in Table 1. To compare the difference

| Table 1. Chemical composition of specimen (mass%). |
|---|---|---|---|---|
| C | Si | Mn | P | Al |
| Steel | 0.08 | 0.7 | 1.15 | 0.015 | 0.04 |
between this steel sheet and the cold-rolled steel sheet produced from it, the hot-rolled steel sheets were ground to a thickness of 1.2 mm, and the unground surface was evaluated. A cold-rolled steel sample was prepared by rolling hot-rolled steel sheets to a thickness of 1.2 mm. Both the hot-rolled and cold-rolled steel samples were precleaned by electric degreasing in an alkaline solution of 3 mass% NaOH at 500 A·m⁻² for 10 s. The samples were then pickled in an acidic solution of 5 mass% HCl at 60°C for 6 s, after they were annealed. Annealing was carried out in an atmosphere of N₂ + 10% H₂ at a dew point of −35°C. The heating rate was 10°C·s⁻¹ up to 400°C followed by heating to the maximum temperature (600–800°C) in 120 s. The soaking time at the maximum temperature was 20 s. After annealing, the samples were rapidly cooled (10°C·s⁻¹) to 460°C and dipped in a molten 0.14 mass% Al–Zn bath. Some of the samples were cooled without dipping in order to analyze the surface condition of the annealed samples. In addition, in order to investigate the temperature dependence of surface selective oxidation, some samples were annealed with the heating rate 12°C·s⁻¹ up to the maximum temperature (600–700°C) and isothermally heated for an arbitrary time (20–600 s).

In the previous studies, the galvanizability of steel sheets was evaluated by a coating grade rating or the numbers of coating defects per unit area. However, both methods were limited to evaluation of the sample appearance, and the reaction between the Zn coating and the base steel was not investigated. Therefore, in this study, the reaction between the Zn coating and the base steel was evaluated by observation Fe–Zn alloy area on the steel surface. A schematic of the Fe–Zn reactivity evaluation by electrical dissolution is shown in Fig. 1. When selectively oxidized Si or Mn existed on the steel surface (Fig. 1(a)), the Fe–Zn alloying reaction was suppressed (Fig. 1(b)). In order to investigate the unreacted area on the steel surface, electrical dissolution was used to reveal the Fe–Zn alloy by dissolving only the η phase (Fig. 1(c)). Fe–Zn reactivity was evaluated based on the observation results of the coverage rate of the Fe–Zn alloy on the steel substrate. The Fe–Zn alloy was revealed by electrical dissolution in a solution of 4 mass% methyl salicylate-1 mass% salicylate acid-10 mass% KI-methanol at −750 mV and 200 A·m⁻².

The annealed samples were analyzed as follows. Selective surface oxidation behavior was investigated by glow discharge optical emission spectroscopy (GDS). A schematic of the GDS measurement results is shown in Fig. 2. The amount of selective surface oxidation of the annealed samples was quantified by measuring the concentration profiles of Si, Mn at the steel surface by GDS. In these GDS profiles, the integrated Si, Mn intensity (arbitrary unit) from the steel surface to the minimal intensity was defined as the amount of selective oxidation.

The morphology of selective surface oxidation of the annealed samples was observed by scanning electron microscopy (SEM). The conditions used in this observation were an acceleration voltage of 1 kV and working distance of 2.4 mm. In order to investigate cross-sectional samples of the annealed samples, samples were prepared by focused ion beam (FIB) milling to a thickness of 100 nm. The samples were investigated by transmission electron microscopy (TEM) to determine the morphology and distribution of the oxides in the subsurface region. In addition, to confirm the factors that deteriorated galvanizability, cross-sectional samples of bare spots on the galvanized samples were also prepared by FIB milling and investigated by TEM.

Determination of the composition of the surface oxides was performed by energy dispersive spectroscopy (EDS) and X-ray photoelectron spectroscopy (XPS). To prepare the samples for XPS analysis, the samples were immediately placed in vacuum storage after annealing to avoid oxidation and corrosion in the atmosphere. Characterization of the species of the oxides on the steel surface was performed using standard oxides powders (Kojundo Chemical Laboratory) as reference samples.

3. Results

3.1. Effect of Annealing Temperature on Galvanizability

3.2. Selective Surface Oxidation Behavior of Si, Mn on Annealed Steel Surface

The selective oxidation behavior of Si, Mn on the annealed steel surface was investigated to clarify the influence of selectively oxidized Si and Mn on Fe–Zn reactivity. Figure 5 shows the GDS depth profiles of the surfaces of the hot-rolled and cold-rolled steels with annealing at 600°C, 700°C and 800°C. With both the hot-rolled and cold-rolled steels, no selective oxidation was detected before annealing. However, on the annealed steel surfaces, selectively oxidized peaks of Si and Mn were observed at several tens of nano-meters from the surface, and these peaks became remarkable with increasing annealing temperature. Figure 6 shows the relationship between annealing temperature and the amount of selective oxidation of Si and Mn of the annealed steel samples. Selective oxidation of both Si and Mn increased with increasing annealing temperature. However, the amount of selective oxidation of the hot-rolled steel was smaller than that of the cold-rolled steel. For example, in the case of annealing at 600°C, selective oxidation peaks were observed on the cold-rolled steel, but no peaks were detected on the hot-rolled steel.

Figure 7 shows the results of SEM observation of the annealed steel surfaces. No precipitates were observed on the surface of hot-rolled steel annealed at the temperatures of 600°C and 650°C, but orbicular precipitates were observed at temperatures over 700°C. On annealed cold-rolled steel, no precipitates were observed at 600°C, and orbicular precipitates were observed at temperatures over 650°C. EDS analysis revealed that the compositions of these orbicular precipitates were Si–Mn–Fe-containing oxides.

XPS was also used to characterize the oxides on the annealed steel surfaces. The results are shown in Fig. 8. Fe$_2$SiO$_4$, Mn$_2$SiO$_4$ and MnSiO$_3$ were used as reference samples, and binding energy of Si 2p was detected. Since Fe$_2$SiO$_4$ and Mn$_2$SiO$_4$ show almost the same energy (101.6 eV) and MnSiO$_3$ also shows relatively similar energy (102.0 eV), the binding energies of these oxides are represented as SiO$_{x^-}$ in Fig. 8. According to the spectrum of Mn 2p and Si 2p in both the hot-rolled and cold-rolled steels, no Mn oxide and a slight SiO$_{x^-}$ peak were detected before anneal-
The existence of an Fe–Si oxide with no Mn content was suggested. However, the peak of Fe–O was mainly detected in the spectrum of Fe 2p before annealing, and the main oxide on the hot-rolled and cold-rolled steels before annealing was confirmed to be Fe oxide. In both the hot-rolled and cold-rolled steels, the peaks of SiO$_x$$^\text{n-}$ and Mn–O

increased with increasing temperature, and these oxides are considered to be the orbicular oxides observed in Fig. 7. In addition, SiO$_2$ was detected after annealing at 800°C. According to the spectra of Fe 2p in both the hot-rolled and cold-rolled steels, the Fe oxide which was the main oxide before annealing decreased proportionally with the formation of SiO$_x$$^{n-}$, and almost no Fe oxide was detected after annealing at 800°C.

### 3.3. Morphology of Oxides on Steel Surface at Low Annealing Temperature

From the investigations described above, a slight amount of Fe oxide was suggested to exist on the steel surface after low temperature annealing. In order to clarify the morphology of the Fe oxide on the surface of the annealed sample, cross-sectional TEM observations were performed. At the same time, the composition of the oxide was investigated by EDS. The results are shown in Fig. 9. On the surfaces of both the hot-rolled and cold-rolled steels before/after annealing at 600°C, uniformly sized thin Fe oxide layers which contained a slight amount of Si, Mn were identified. As the temperature increased, the morphology of the Fe oxide layer changed to island-shaped precipitates. This change occurs at the temperatures of 700°C on the annealed sample of the hot-rolled steel and at 650°C on the annealed cold-rolled steel. From the EDS analysis results shown in Table 2, these island-shaped precipitates were confirmed to be Fe–Si–Mn-containing oxides. In the region surrounded by the island-shaped precipitates (circled area in the figure), the Fe oxide layer had almost disappeared, and the steel surface was exposed.

**Table 2.** Chemical composition at point marked in Fig. 9 (mol%).

|          | Fe  | Si  | Mn  | O   |
|----------|-----|-----|-----|-----|
| EDS①     | 96.8| 0.0 | 0.3 | 2.9 |
| EDS②     | 13.2| 20.8| 16.5| 49.5|

To confirm the influence of this change in the morphology of the oxides on the wettability of the Zn coating, cross-sectional TEM observation of the interface between a bare spot and galvanized area was performed. **Figure 10** shows...
the results of observation of the galvanized cold-rolled steel after 650°C annealing, at which the formation of orbicular oxides was observed. In the bare spot, no Si–Mn orbicular oxides were observed, but a thin Fe oxide layer was observed. On the other hand, Si–Mn orbicular oxides were observed in the galvanized area.

4. Discussion

4.1. Change in Amount of Selective Surface Oxidation with Annealing Temperature and Its Effect on Fe–Zn Reactivity

The effect of selective surface oxidation on wettability in galvanizing has been investigated in many studies, which found that selective surface oxidation of Si and Mn deteriorates galvanizability.6–13) In order to clarify the effect of selective surface oxidation on Fe–Zn reactivity, in this study, the relationship between the unreacted area fraction (Fig. 4) and the amount of selective surface oxidation (Fig. 6) was considered. According to Fig. 6, the temperature dependence of Si and Mn selective oxidation were almost same, and Fig. 11 shows the relationship between unreacted area fraction and the amount of Si selective oxidation (a.u.). A shaded area in the figure represents the conditions of the minimum unreacted area fraction (hot-rolled steel: 700°C, cold-rolled steel: 650°C) in this study.

The Fe–Zn reactivity of the cold-rolled steel deteriorated with increasing temperature above 650°C. This result coincided with the results of previous studies showing that selective surface oxidation of Si and Mn deteriorate Fe–Zn reactivity. However, in the case of the hot-rolled steel, Fe–Zn reactivity deteriorated with increasing temperature above 700°C. Thus, the results of this investigation suggested that Fe–Zn reactivity has a good correlation with the amount of Si, Mn selective oxidation above an annealing temperature of 700°C.

However, in the low annealing temperature region indicated by the circle in Fig. 11, the Fe–Zn reactivities of both the hot-rolled steel and the cold-rolled steel deteriorated. This suggests that some deteriorating factor other than selective oxidation exists in the low annealing temperature region. Therefore, the deteriorating factors of Fe–Zn reactivity at low annealing temperatures are considered in the following section.

4.2. Factors Affecting Galvanizability at Low Annealing Temperature

From the XPS results in Fig. 8, Fe oxide existed on the surfaces of both the hot-rolled and cold-rolled steels before annealing. There were no differences in both the composition and morphology of these oxides in the hot-rolled and cold-rolled steels, and these oxide films were suggested to be native Fe oxide. It has been reported that these oxide layers deteriorate galvanizability.32) Especially at low annealing temperatures, the Fe oxide layer was found to cover the steel surface as shown in Fig. 9. Therefore, this residual Fe oxide layer is considered to be a main deteriorating factor at low annealing temperatures.

Then, the mechanism by which the Fe–Zn reactivities of the hot-rolled steel and cold-rolled steel were improved with increasing temperature was considered. During the annealing process, surface selective oxidation was considered to occur by the reaction of diffused Si, Mn from the steel substrate and the dissociated oxide from H2O in the atmosphere.33) However, if the steel surface is covered by an Fe oxide layer, the diffused Si and Mn may have the potential to react with the residual Fe oxide. To confirm this
hypothesis, the following reactions in connection with the oxidation of Si and Mn-bearing steel in an atmosphere with \( \text{H}_2-\text{H}_2\text{O} \) were calculated.

\[
\begin{align*}
\text{Fe} + \text{H}_2\text{O} &= \text{FeO} + \text{H}_2 \quad \text{(1)} \\
2\text{Fe} + \text{SiO}_2 + 2\text{H}_2\text{O} &= 2\text{FeSiO}_4 + 2\text{H}_2 \quad \text{(2)} \\
\text{Mn} + \text{H}_2\text{O} &= \text{MnO} + \text{H}_2 \\n\text{(3)} \\
\text{Mn} + \text{SiO}_2 + \text{H}_2\text{O} &= \text{MnSiO}_3 + \text{H}_2 \quad \text{(4)} \\
\text{Si} + 2\text{H}_2\text{O} &= \text{SiO}_2 + 2\text{H}_2 \\n\text{(5)}
\end{align*}
\]

\( p_{\text{H}_2\text{O}}/p_{\text{H}_2} \) is defined as the ratio of the partial pressure of \( \text{H}_2\text{O} \) \( (p_{\text{H}_2\text{O}}) \) and that of \( \text{H}_2 \) \( (p_{\text{H}_2}) \). \( p_{\text{H}_2\text{O}}/p_{\text{H}_2} \) of each oxide was calculated considering the above Eqs. \( (1) \) through \( (5) \) for an Fe-0.7 mass% Si-1.15 mass% Mn alloy annealed in an atmosphere of 10 vol% \( \text{H}_2-\text{N}_2 \) \( 34,35 \). The results are shown in Fig. 12. \( \log(p_{\text{H}_2\text{O}}/p_{\text{H}_2}) \) could be calculated at about –2.66 in the annealing atmosphere, which had a dew point of –35°C and a hydrogen concentration of 10 vol%. As shown in Fig. 12, when \( \log(p_{\text{H}_2\text{O}}/p_{\text{H}_2}) \) equals –2.66, the reaction in Eqs. \( (1) \) and \( (2) \) should proceed to the left, and Eqs. \( (3) \) through \( (5) \) should proceed to the right. These results also suggest that Si–Mn composite oxides are more stable than Fe oxide. Therefore, when the surface of the steel is covered by an Fe oxide layer, diffused Si and Mn have the potential to react with the residual Fe oxide. This indicates that the following reaction occurred at the steel surface under the low annealing temperature conditions.

\[
\text{FeO}_x + y \text{Mn} + z \text{Si} \rightarrow \text{Fe}_{1-x}\text{Mn}_y\text{Si}_z\text{O}_x + x \text{Fe} \quad \text{(6)}
\]

According to Eq. \( (6) \), Fe oxide is reduced and active Fe is produced during the oxidation of Si and Mn. This Si–Mn composite oxide tends to form in an orbicular shape. \( 36 \) Therefore, when the reduction of Fe oxide proceeded as shown in Eq. \( (6) \) with increasing temperature, active Fe was produced with the formation of Si–Mn composite orbicular oxides, and Fe–Zn reactivity was considered to be improved. This result can explain the phenomenon shown in Fig. 10 that no Si–Mn orbicular oxides were detected but a thin Fe oxide layer was observed in the bare spot area, while Si–Mn orbicular oxides were observed in the galvanized area. Figure 13 shows schematic illustrations of the reduction mechanism of the Fe oxide layer at low annealing temperatures.

### 4.3. Rate-determining Process of Surface Segregation at Low Annealing Temperature

In this section, the Fe–Zn reactivity of the hot-rolled steel was substantially worse than that of the cold-rolled steel in the low annealing temperature region. In addition, the temperatures at which Fe–Zn reactivity improved were also different between the hot-rolled and cold-rolled steels. However, the species of the oxides and the reduction mechanism of the Fe oxide on the hot-rolled and cold-rolled steels were the same. Therefore, the difference in Fe–Zn reactivity between the hot-rolled steel and the cold-rolled steel at low annealing temperatures was considered to be due to the difference in the reduction rate of Fe oxide, that is, the difference in the segregation rates of Si and Mn. Selective surface oxidation consists of two different processes: One is the diffusion of the element concerned from the steel substrate, and the other is the reaction with the atmosphere on the steel surface. Therefore, the difference in the segregation rates is considered to be due to the “diffusion rate,” which depends on the structure of the steel surface, or the “reaction rate,” which depends on the steel surface condition.

First, the possibility of a difference in the diffusion rate of Si and Mn in the hot-rolled steel and cold-rolled steel was investigated. There are cases in which the diffusion rate in the steel subsurface region changes. One is the existence of a Si- and Mn-depleted area in the steel subsurface region; in this case, diffusion of these elements is suppressed. \( 37-39 \) The other is a change in the structure of the steel surface due to the strain that occurs in the cold-rolling process, in this case diffusion of the elements is accelerated. \( 40-43 \) As for the former case, because no depleted area was observed
in the subsurface region of the hot-rolled steel, as shown in Fig. 5, depletion was considered to have little effect on the segregation rate. Thus, the difference in the segregation rates of the hot-rolled and cold-rolled steels can presumably be attributed to the strained structure that occurred in the cold-rolling process.

Therefore, whether the “diffusion rate” or “reaction rate” is the main determining process of the segregation rate will be discussed in detail in the following paragraph. In order to investigate the time dependence of surface selective oxidation, samples were annealed at the maximum temperature of 600–700°C and isothermally heated for an arbitrary time (20–600 s). Above results are shown in Fig. 14. In the figures, “n” represents the slope of the lines estimated by least-squares method, and each line has almost the same value of 0.5. This result shows that the segregation rates of both Si and Mn follow the parabolic law. This means that the segregation rates of Si and Mn at low annealing temperatures were determined not by the “reaction rate,” but by the “diffusion rate.”

The investigation presented the fact that the segregation mechanisms of both the hot-rolled steel and the cold-rolled steel are determined by the “diffusion rate.” Therefore, it is suggested that the difference in the segregation rates of Si and Mn between the hot-rolled steel and cold-rolled steel is due to strain during the cold-rolling process.

Finally, the difference in Fe–Zn reactivity between the hot-rolled steel and the cold-rolled steel in the low annealing temperature region is summarized. On the hot-rolled steel surface, the diffusion rates of Si and Mn are so slow that the formation of Si–Mn composite oxides is suppressed and the reduction of Fe oxide is also delayed. Therefore, Fe oxide has a large effect on the surface of hot-rolled steel at low annealing temperatures, and as a result, the Fe–Zn reactivity of the hot-rolled steel is worse than that of the cold-rolled steel under the same annealing conditions. Moreover, in the case of the hot-rolled steel, a higher annealing temperature is necessary to diffuse sufficient amounts of Si and Mn to
reduce the Fe oxide. For these reasons, the Fe–Zn reactivity of the hot-rolled steel was substantially worse than that of the cold-rolled steel at low annealing temperatures. **Figure 15** shows schematic illustrations of the selective oxidation behaviors of the hot-rolled and cold-rolled steels annealed at low annealing temperatures.

5. Conclusion

In order to clarify the factors that affect the galvanizability of hot-rolled and cold-rolled steels, hot-rolled and cold-rolled steel sheets containing 0.7 mass% Si-1.2 mass% Mn were annealed at various temperatures in the range of 600–800°C, and their selective surface oxidation behavior and its effect on Fe–Zn reactivity were investigated. The results of the present study are summarized as follows.

(1) As the annealing temperature increased, the Fe–Zn reactivity of both the hot-rolled and cold-rolled steels deteriorated with an increasing amount of selectively oxidized Si, Mn above 700°C and 650°C, respectively.

(2) The Fe–Zn reactivities of the hot-rolled steel and cold-rolled steel deteriorated with an increasing amount of selectively oxidized Si, Mn above 700°C and 650°C, respectively.

(3) At the annealing temperatures lower than 650°C, a uniform Fe oxide layer remained on the steel surface, and this layer deteriorated Fe–Zn reactivity. It was suggested that this Fe oxide reacted with Si, Mn which diffused from the steel substrate, and orbicular Si–Mn oxides were formed. Consequently, the Fe oxide layer was reduced, and the Fe–Zn reactivity at low annealing temperatures improved.

(4) The Fe–Zn reactivity of the hot-rolled steel at low annealing temperatures was substantially worse than that of the cold-rolled steel. This can be explained by the slow reduction of Fe oxide due to the low selective oxidation rate of the hot-rolled steel.
