(Dated: April 20, 2020)

The two-dimensional nature of graphene Josephson junctions offers the possibility of creating effective superconductor-ferromagnet-superconductor junctions with tunable Zeeman splitting caused by an in-plane magnetic field. Such junctions would be able to alternate between a conventional superconducting ground state and a ground state with an intrinsic phase difference, making them controllable 0-\(\pi\) Josephson junctions. However, in addition to the Zeeman splitting, an in-plane magnetic field will in general also produce an orbital effect because of height variations in graphene, colloquially known as ripples. Both the Zeeman and orbital effect will thus affect the critical current, so to be able to identify 0-\(\pi\) transitions it is necessary to understand their combined effect. From both analytical and numerical solutions of the Usadel equation we find that ripples can in fact produce a current response similar to that which is characteristic of a 0-\(\pi\) transition. Hence, additional analysis is required in order to reveal the presence of a 0-\(\pi\) transition caused by spin-splitting in graphene with ripples. We provide a closed form analytical expression for the critical current in the presence of exchange field and ripple effects as well as an expression for the scaling of critical current zeroes with junction parameters.

I. INTRODUCTION

When the spinless superconducting order of a conventional superconductor comes in contact with a ferromagnet, it can adapt by creating spin-triplet Cooper pairs [1]. The synergy between superconductivity and ferromagnetism, two seemingly incompatible orders, is a topic of fundamental interest, but could also be of practical value. One interesting consequence is that it allows for spinfull supercurrents. The promise of low-dissipation spin transport has helped spawn the field of superconducting spintronics [2].

In the last decade, the possibility of creating Josephson junctions with graphene has attracted interest [3–7]. Superconductor-graphene-superconductor (SGS) junctions provide an arena for understanding the interplay between superconductivity and otherwise distinct physical phenomena, such as special relativity [3] and the quantum Hall effect [8, 9]. Here, we are interested in how the two-dimensional nature of monolayer graphene can be utilized to create an effective superconductor-ferromagnet-superconductor (SFS) junction with a tunable exchange field. This is done by introducing a Zeeman splitting between the spin-bands in the graphene by use of a strong in-plane magnetic field. This is possible because the two-dimensional nature of the graphene minimizes the magnetic depairing effect that would otherwise quench the superconducting correlations. By using electrodes with Ising-like superconductivity, like thin NbSe2, one avoids destroying the superconducting state of the electrodes via the Pauli limitation.

The possibility of in situ control of the exchange field could open new avenues for manipulations that take advantage of the combined effect of magnetic and superconducting order. In addition to giving rise to the possibility of Cooper pairs with non-zero total spin [2], the presence of a magnetic field gives the Cooper pairs a non-zero total momentum, as first explained by Fulde, Ferrel, Larkin and Ovchinnikov [10, 11]. The total momentum of the Cooper pairs in the so-called FFLO-state is given by the strength of the exchange field, as this determines the displacement of the two Fermi surfaces corresponding to spin-up and spin-down electrons. The non-zero momentum produces spatial variations in the superconducting order parameter [12].

One consequence of the spatial variations, is that the ground state of a superconductor-ferromagnet-superconductor (SFS) Josephson junction can be one in which the phases of the order parameter in the two superconductors differs by \(\pi\), which is known as a \(\pi\)-junction. Such junctions could have an important role in the design of components for quantum computing [13–15], superconducting computing [16, 17] or as cryogenic memory [18].

Whether an SFS-junction is a \(\pi\)-junction or not depends on its length as well as the strength of the exchange field, which are typically fixed parameters. If, however, the exchange field could be tuned, this would allow for a controllable switching between the 0-junction state and \(\pi\)-junction state. Zeeman-effect-induced 0-\(\pi\) transitions have previously been observed in a Dirac semimetal with a \(g\) factor on the order of 103 [19]. The large \(g\) factor allowed the 0-\(\pi\) transition to occur before the magnetic field extinguished the superconducting correlations. Using a junction with a two-dimensional material, such as monolayer graphene, would allow for Zeeman driven 0-\(\pi\) transitions without the need for large \(g\) factors, since such junctions can withstand much larger in-plane magnetic fields.

The prospect of a graphene Josephson junction being used as a tunable SFS-junctions is interesting, but it also demands a thorough investigation into how the supercurrent in an SGS-junction responds to the strong in-plane magnetic field necessary for an appreciable Zeeman splitting. Even though monolayer graphene is two-dimensional, it will in general not be perfectly flat. It will have a curvature that depends on the underlying substrate. If the graphene is placed on SiO2, it will be rippled with peak-to-peak height difference of about 1 nm and typical feature size of 30 nm [20]. Hence, the in-plane magnetic field will have a component orthogonal to the graphene surface, giving rise to an orbital effect. This orthogonal component has been observed to suppress phase-coherent weak localization [21, 22]. Consequently, extra care must be taken when considering phase-coherent transport experiments relying on...
in-plane magnetic fields. Here, we show that attention must also be paid to ripples when considering SGS-junction with tunable Zeeman splitting.

![Diagram of superconductor-graphene-superconductor junction with ripples and external magnetic field](image)

**Fig. 1**: Sketch of superconductor-graphene-superconductor junction with rippled graphene and external magnetic field. The magnetic field has out-of-plane component \( B_z \) and in-plane components \( B_x \) and \( B_y \).

One property of a 0-\( \pi \) transition is that the current changes sign, giving zero net current exactly at the transition \[23\]. Characterization of an SGS-junction and the identification of a possible 0-\( \pi \) transition will typically be done by measuring the current response to an applied magnetic field. Therefore, it is important to know whether features in the critical current, such as the decay rate and zeros, can also be produced by an interference effect that arises from ripples in the graphene. Of particular interest is whether interference effects can give a vanishing critical current at magnetic field strengths that are comparable to the magnetic field necessary for a 0-\( \pi \) transition. The Zeeman energy necessary for the transition is typically smaller for diffusive systems \[12\], so diffusive systems are most promising for tunable \( \pi \)-junctions. However, computing the supercurrent in a model with ripples in graphene is a challenging task due to the non-trivial geometry of the system.

A sketch of the system under consideration is shown in fig. 1. In order to model this geometry, we add a spatially varying magnetic field to the equations governing diffusive SFS-junctions, where the exchange field in the ferromagnet comes from the Zeeman effect. In order to fully model the disorderly ripples, one must be able to solve the equations with arbitrary magnetic field distributions. We are able to do that numerically by using the finite element method. Additionally, we extend the analytical result by Bergeret and Cuevas \[24\] for superconductor-normal-superconductor (SNS) junctions with uniform magnetic fields to SFS-junctions with arbitrary magnetic field distributions and arbitrary exchange fields.

**II. METHODOLOGY**

The critical current, as well as other physical quantities such as the local density of states, can be calculated using the quasiclassical Keldysh Green’s function formalism \[25, 26\]. Previous studies of ballistic systems have investigated the interplay of the Zeeman and the orbital effect using an analytical propagator approach \[27, 28\]. The diffusive limit considered here, however, is more appropriately described by the Usadel equation, which previously has been done to successfully model experimental results for the supercurrent in SGS junctions \[29\]. We use natural units throughout, meaning that \( c = \hbar = 1 \).

In thermal equilibrium it is sufficient to solve for the retarded Green’s function, \( \tilde{g} \), which is normalized to \( \tilde{g}^2 = 1 \) and solves the Usadel equation,

\[
D \nabla \cdot (\hat{g} \nabla \hat{g}) + i [\Sigma, \hat{g}] = 0, \tag{1}
\]

provided that the Fermi wavelength and the elastic impurity scattering time is much shorter than all other relevant length scales, and the Fermi wavelength is much smaller than the scattering time. Here \( D \) is the diffusion coefficient and the covariant derivative is \( \nabla \hat{g} \equiv \nabla \hat{g} - i e \Lambda [\hat{\rho}_3, \hat{g}] \), where \( \Lambda \) is the vector potential. The self-energy is

\[
\Sigma = \begin{cases} 
(\epsilon + i \delta) \hat{\rho}_3 + \left( \begin{array}{c} \Delta \\ \Delta^* \\ -\Delta^* \\ -\Delta \\ \hat{h} \cdot \sigma \end{array} \right) & \text{in the superconductors,} \\
(\epsilon + i \delta) \hat{\rho}_3 + \left( \begin{array}{c} \hat{h} \cdot \sigma \end{array} \right) & \text{in the ferromagnet,}
\end{cases} \tag{2}
\]

where \( \epsilon \) is the energy, \( \delta \) is the inelastic scattering time, \( \hat{\rho}_3 = \text{diag}(1, 1, -1, -1) \), \( \Delta \) is the superconducting gap parameter, \( \hat{h} \) is the exchange field and \( \sigma \) is the vector consisting of Pauli matrices. Defining “spin up” and “spin down” parallel to the in-plane magnetic field gives \( \hat{h} = h \hat{z} \). We here disregard the effect of the very weak \( k \)-dependent spin-orbit induced effective Zeeman-field caused by ripples in graphene, which is opposite in direction at the two inequivalent Dirac points of graphene \[30\].

Let \( x \) and \( y \) be an orthogonal coordinate system of the graphene surface such that the superconductors are located at \( x = \pm L/2 \) and the interfaces with vacuum are at \( y = \pm W/2 \). The curved geometry of graphene will in general enter into the Usadel equation \(1\) in two ways. First, the divergence operator is altered by the presence of nonzero Christoffel symbols. However, since the curvature of rippled graphene typically is very small \[20\], this effect is negligible. Consequently, we use \( \nabla \equiv \hat{\xi} \frac{\partial}{\partial x} + \hat{\xi} \frac{\partial}{\partial y} \). Second, and crucial for the effect considered here, the in-plane magnetic field has a component orthogonal to the surface. In the external coordinate system, or “lab frame”, the magnetic field can be written \( \mathbf{B} = (B_x, B_y, B_z)^	op \), as illustrated in fig. 1, but in the coordinate system of the curved graphene, the magnetic field has a \( z \)-component equal to

\[
\mathbf{B} \cdot \hat{z} = -B_z \sin \left[ \arctan \left( \frac{\partial \eta}{\partial x'} \right) \right] - B_y \sin \left[ \arctan \left( \frac{\partial \eta}{\partial y'} \right) \right] + B_z \approx -B_x \frac{\partial \eta}{\partial x} - B_y \frac{\partial \eta}{\partial y} + B_z, \tag{3}
\]

where \( \eta \) is the height distribution of the graphene, \( x' \) and \( y' \) are the coordinates in the lab frame and we have used the assumption
that \( \partial \eta / \partial x \approx \partial \eta / \partial x' \ll 1 \) and \( \partial \eta / \partial y \approx \partial \eta / \partial y' \ll 1 \). We have also neglected the modulation effect that the curvature has on the out-of-plane magnetic field component \( B_z \), since this only gives a contribution that is negligible compared to that of the much larger in-plane field, given by \( B_x \) and \( B_y \).

In order to capture the magnetic field given by eq. (3), we use the vector potential \[ A = \left( B_y \eta + B_x \int_0^y \frac{\partial \eta}{\partial x} d\tilde{y} - B_z \phi \right) \hat{x}. \] Choosing the vector potential parallel to the \( x \)-axis allows us to set \( A = 0 \) in the superconductors, which means that the ground states in the superconductors have constant phases. In the following we denote the superconducting phase in the left \((x < -L/2)\) and right \((x > L/2)\) superconductors by \( \phi_l \) and \( \phi_r \), respectively.

The Usadel equation \(1\) is not valid across boundaries of different materials since the associated length scales are not negligible compared to the Fermi wavelength. Instead, the Green’s function in the different materials must be connected through a boundary condition. For low-transparency tunneling interfaces, one may use the Kupriyanov-Lukichev boundary condition \([31]\),

\[ \zeta L_i \hat{n} \cdot (\hat{g}_i \nabla \hat{g}_i) = \frac{1}{2} [\hat{g}_i, \hat{g}_j], \tag{5} \]

where the subscripts \( i \) and \( j \) denote the different sides of the interface, \( \hat{n} \) is a normal unit vector pointing out of region \( i \), \( L_i \) is the length of region \( i \) in the \( \hat{n} \)-direction and \( \zeta_i \) is the ratio of the normal-state conductance of region \( i \) to the interface conductance. Equation (5) is used along the interface between the superconductors and graphene at \( x = -L/2 \) and \( x = L/2 \). Along the boundaries with vacuum at \( y = \pm W/2 \), the boundary condition is \( \hat{n} \cdot \nabla \hat{g} = 0 \).

It has been shown that one may use the bulk solution in the superconductors,

\[ \hat{g}_{\text{ncs}} = \frac{\Sigma}{\sqrt{(\varepsilon + i \delta)^2 - |\Delta|^2}}, \tag{6} \]

when the interface conductance is much smaller than the normal-state conductance of length \( \xi \) of the superconductor \([32]\), where

\[ \xi = \sqrt{\frac{D}{\Delta}} \tag{7} \]

is the coherence length. The square root in eq. (6) must be chosen such that it has a positive imaginary part.

Having found the Green’s function, the electrical current density can be calculated from \([33]\)

\[ j = \frac{N_0 e D}{4} \int_{-\infty}^{\infty} \text{Tr} \left( \hat{\rho}_3 \hat{g} \nabla \hat{g} - \hat{g}^\dagger \nabla \hat{g}^\dagger \hat{\rho}_3 \right) \tanh \left( \frac{\beta \varepsilon}{2} \right) d\varepsilon, \tag{8} \]

where \( N_0 \) is the normal density of states and \( \beta \) is inverse temperature. Finally, eq. (8) allows for calculation of the critical current, given by

\[ I_c = \max_{\phi_r - \phi_l} \int_{-W/2}^{W/2} \hat{n} \cdot j(x, y) dy, \tag{9} \]

where the choice of \( x \) is arbitrary.

In order to solve eq. (1) numerically, we use the Ricatti parametrization,

\[ \hat{g} = \left( \begin{array}{cc} N & 1 + \gamma \tilde{g} \\ -\tilde{N} & 1 + \gamma \tilde{g} \end{array} \right), \tag{10} \]

where \( N = (1 - \gamma \tilde{g})^{-1} \) and tilde conjugation is defined as \( \tilde{g}(\varepsilon) = g(\varepsilon'). \) This respects the normalization and underlying symmetries of \( \hat{g} \). The resulting equations for the \( 2 \times 2 \) matrices \( \gamma \) and \( \tilde{g} \) are discretized by the finite element method \([34]\) with quadratic elements, and Gauss-Legendre quadrature rules of fourth order is used to integrate over the elements. The resulting nonlinear set of algebraic equations are solved by the Newton-Raphson method \([35]\), where the Jacobian is determined by forward-mode automatic differentiation \([36]\).

III. RESULTS AND DISCUSSION

In order to linearize the Usadel equation, we write

\[ \hat{g} = \hat{g}_0 + \hat{f}, \tag{11} \]

where \( \hat{g}_0 \) is the bulk solution. In a ferromagnet, the self-energy \( \Sigma \), given by eq. (2), is diagonal. Hence, the bulk equation \([\Sigma, \hat{g}_0] = 0 \) is solved by any diagonal matrix satisfying \( \hat{g}_0^2 = 1 \).

In order to find the correct solution one must solve the full Gor’kov equation. The result is that \( \hat{g}_0 = \hat{\rho}_3 \). If we assume that the proximity effect is weak, we can keep only linear terms in \( \hat{f} \), yielding

\[ D \hat{\rho}_3 \nabla^2 \hat{f} + i [\Sigma, \hat{f}] = 0, \tag{12} \]

In order for the normalization \( g^2 = 1 \) to hold to linear order in \( \hat{f} \), we need \( \{ \hat{f}, \hat{\rho}_3 \} = 0 \). This implies that

\[ \hat{f} = \left( \begin{array}{c} 0 \\ -\hat{f} \end{array} \right), \tag{13} \]

and

\[ \nabla \hat{f} = \nabla \hat{f} - 2 i e A \hat{\rho}_3 \hat{f}. \tag{14} \]

In the weak proximity effect regime, the boundary conditions read

\[ \zeta L_i \hat{n} \cdot (\hat{g}_i \nabla \hat{g}_i) = \frac{1}{2} [\hat{\rho}_3 + \hat{f}, \hat{g}_s + \hat{f}_s] = \hat{\rho}_3 \hat{f}_s - \hat{g}_s \hat{f}, \tag{15} \]

where \( \hat{g}_s \) is the part of \( \hat{g}_{\text{ncs}} \) proportional to \( \hat{\rho}_3 \) and \( \hat{f}_s \) is the remaining part proportional to \( \text{antidiag}(\Delta, -\Delta^*, -\Delta^*) \). Additionally, we must have \( \{ \hat{f}_s, \hat{f}_s \} = 0 \), since this term would be block diagonal.

Since \( \Sigma \) is diagonal in the ferromagnet, the different components of \( \hat{f} \) decouple. Only the elements which are nonzero in \( \hat{f}_s \) will have a constant term in the boundary conditions. The remaining elements must be zero. Hence, \( \hat{f} \) must be antidiagonal, just like \( \hat{f}_s \). This in turn implies that \([\Sigma, \hat{f}] = 2 \Sigma \hat{f} \).
In order to solve the Usadel equation for arbitrary magnetic fields, we first define
\[
\hat{u} = \exp\left(-2ie\hat{\rho}_3 \int_{-L/2}^{x} A(x', y) \, dx'\right) \tilde{f}
\] (16)

With this, the Usadel equation can be written
\[
D\hat{\rho}_3 \nabla^2 \hat{u} + 2i\hat{\Sigma} \hat{u} - 2De \hat{\rho}_3 \hat{u} \int_{-L/2}^{x} \frac{\partial B}{\partial y} \, dx' - 4De^2 \hat{u} \left(\int_{-L/2}^{x} B \, dx' \right)^2 - 4De \frac{\partial \hat{u}}{\partial y} \int_{-L/2}^{x} B \, dx' = 0,
\] (17)

where we have used that \(B = -\partial A/\partial y\). We can neglect the terms involving \(B\) (the magnetic field component orthogonal to the graphene) by assuming that the magnetic field is sufficiently weak. That is, for all \(x \in (-L/2, L/2)\),
\[
\int_{-L/2}^{x} B \, dx' \ll \Phi_0 \sqrt{D},
\] (18a)
and
\[
\int_{-L/2}^{x} \frac{\partial B}{\partial y} \, dx' \ll \Phi_0 \frac{\delta}{D},
\] (18b)

where \(\Phi_0 = \pi/e\) is the magnetic flux quantum.

The boundary conditions for \(\hat{u}\) at \(y = \pm W/2\) is
\[
\left.\frac{\partial \hat{u}}{\partial y}\right|_{y=\pm W/2} = -i\hat{u} \int_{-L/2}^{x} B \, dx'.
\] (19)
Equations (15), (17) and (19) can be solved exactly when \(B = 0\) by assuming \(\partial^2 \hat{u}/\partial y^2 = 0\). For \(B\) satisfying eq. (18) we can find an approximate solution by neglecting the term \(\partial^2 \hat{u}/\partial y^2\) in eq. (17).

With these approximations, the Usadel equation becomes an ordinary differential equation,
\[
\frac{\partial^2 \hat{u}}{\partial x^2} + \frac{2i\hat{\rho}_3 \hat{\Sigma}}{D} \hat{u} = 0,
\] (20)
with solution
\[
\hat{u} = e^{\hat{k}x} \hat{A} + e^{-\hat{k}x} \hat{B},
\] (21)
for some coefficients \(\hat{A}\) and \(\hat{B}\). Here
\[
\hat{k} = \sqrt{-\frac{2i\hat{\rho}_3 \hat{\Sigma}}{D}},
\] (22)
which, since \(\hat{\rho}_3 \hat{\Sigma}\) is diagonal, \(\hat{k}\) can be obtained simply by taking the elementwise square root. To determine \(\hat{A}\) and \(\hat{B}\) one must use eq. (15). The solution is
\[
\hat{u} = \left(\zeta L \hat{k} + \hat{\rho}_3 \hat{g}_s\right)^2 e^{\hat{k}L} - \left(\zeta L \hat{k} - \hat{\rho}_3 \hat{g}_s\right)^2 e^{-\hat{k}L}\right)^{-1} \times \left[\hat{\rho}(-x) + e^{i\hat{\rho} \theta} \hat{\rho}(-x)\right] \tilde{f},
\] (23)
where
\[
\theta = \phi_r - \phi_l + 2e \int_{-L/2}^{L/2} A(x, y) \, dx
\] (24)
and
\[
\hat{\rho}(x) = (\zeta L \hat{k} + \hat{\rho}_3 \hat{g}_s)e^{\hat{k}(x-L/2)} + (\zeta L \hat{k} - \hat{\rho}_3 \hat{g}_s)e^{-\hat{k}(x-L/2)}.
\] (25)

Note that the boundary condition for the interfaces with vacuum, eq. (19), is only approximately satisfied.

To find the current from eq. (23) we can use that the \(x\)-component of the current, as given by eq. (8) can be written
\[
j \cdot \hat{\kappa} = \frac{N_0 e D}{4} \int_{-\infty}^{\infty} \text{Tr} \left(\hat{\rho}_3 \hat{u} \frac{\partial \hat{u}}{\partial x} - \hat{u} \frac{\partial \hat{u}^\dagger \hat{\rho}_3}{\partial x} \right) \tan \left(\frac{\beta e}{2}\right) \, de
\] (26)
To simplify this expression, note that eq. (23) can be written
\[
\hat{u} = \begin{pmatrix}
\hat{d}(h)e^{i\phi_l} \\
\hat{d}(h)e^{-i\phi_l}
\end{pmatrix}
\] (27)
where
\[
d(h) = \frac{[\rho(x) + e^{i\theta} \rho(-x)]|\Delta|}{\sqrt{(\zeta L k + g_s)^2 e^{kL} - (\zeta L k - g_s)^2 e^{-kL}}}.
\] (28)

with \(g_s = (e + i\delta)/\sqrt{(e + i\delta)^2 - |\Delta|^2}\), the square roots are those which have positive imaginary parts, \(k = \sqrt{-2i(e + h + i\delta)/D}\) and
\[
\rho(x) = (\zeta L k + g_s)e^{k(x-L/2)} + (\zeta L k - g_s)e^{-k(x-L/2)}.
\] (29)

Inserting eq. (28) into eq. (26) gives
\[
j \cdot \hat{\kappa} = \frac{N_0 e D}{4} \int_{-\infty}^{\infty} \text{Re} \left[\frac{\partial \hat{d}(h)}{\partial x} + \frac{\partial \hat{d}(h)}{\partial x}\right] \tan \left(\frac{\beta e}{2}\right) \, de.
\] (30)

By evaluating \(j\) at \(x = 0\) we can factorize out the dependence on the vector potential, since
\[
\left.\frac{\partial \hat{d}(h)}{\partial x}\right|_{x=0} = \frac{2i \sin \theta}{1 + e^{i\theta}} \times \frac{\partial \ln p}{\partial x} \left(d(-h)\right)_{x=0}.
\] (31)

Inserting this into eq. (30) and integrating the current density over \(y\) to obtain the total current finally gives
\[
I = 2N_0 e D \int_{-W/2}^{W/2} \sin \left(\phi_r - \phi_l + 2e \int_{-L/2}^{L/2} A(x, y) \, dx\right) dy \times \int_{-\infty}^{\infty} \text{Im} \{\kappa_+ + \kappa_-\} \tan \left(\frac{\beta e}{2}\right) \, de,
\] (32)
where
\[
\kappa_{\pm} = \frac{4|\Delta|^2 \kappa_{\pm}}{(\varepsilon + i\delta)^2 - |\Delta|^2} \times \frac{[\zeta L k_{\pm} \cosh(k_{\pm}L/2) - g_{\pm} \sinh(k_{\pm}L/2)] \times [\zeta L k_{\pm} \sinh(k_{\pm}L/2) - g_{\pm} \cosh(k_{\pm}L/2)]}{[(\zeta L k_{\pm} + g_{\pm})^2 e^{k_{\pm}L} - (\zeta L k_{\pm} - g_{\pm})^2 e^{-k_{\pm}L}]^2},
\]

(33)

with \(k_{\pm} = \sqrt{-2i(\varepsilon \pm h + i\delta)/D}\).

Equation (32) is our main analytical result and allows for evaluation of the current at arbitrary exchange field strengths and magnetic field distributions. Of particular interest is the fact that the contribution from the vector potential and exchange field decouples. One consequence of this is that a constant magnetic field gives rise to a Fraunhofer pattern in the current regardless of the strength of the exchange field, as long as the magnetic field is weak enough. This can be seen from the fact that for a constant magnetic field \(eA = -\pi \Phi y/\Phi_0 WL\), where \(\Phi_\perp\) is the magnetic flux from the perpendicular field, so

\[
I \propto \int_{-W/2}^{W/2} \sin \left(\phi_x - \phi_l - 2\pi \frac{\Phi y}{\Phi_0 W}\right) dy = -W \sin(\phi_x - \phi_l) \sin\left(\frac{\pi \Phi y}{\Phi_0 W}\right). \tag{34}
\]

Figure 2 shows the critical current found analytically using eq. (32) for the case of no ripples, compared to the critical current obtained numerically from the full nonlinear Usadel equation. In addition to showing the agreement between the full solution and the analytical approximation, fig. 2 also shows that there is an exchange-driven 0-\(\pi\) transition at \(h \approx 2\varepsilon_t\), where

\[
\varepsilon_t = \frac{D}{L^2} \tag{35}
\]

is the Thouless energy.

\[
\begin{align*}
\text{FIG. 2: Color plot of } & \log_{10}(I_c/I_0) \text{, where } I_c \text{ is the critical current and } I_0 = N_0 e WD^2/L^3 \text{ for various exchange fields } h \text{ and out-of-plane magnetic fluxes. Figure a) shows the solution found numerically from the full Usadel equation, and b) shows the analytical solution found using eq. (32). Here, } \\
& e_t = D/L^2, \ W = 10L, \ L = 6\xi, \ \delta/\Delta = 0.01 \text{ and } \ B_x = B_y = 0. \\
& \text{Since the contribution from the exchange field is independent of the vector potential, we can focus on how the magnetic field alters the critical current. With the vector potential given by eq. (4), we get} \\
& \int_{-L/2}^{L/2} A(x, y) \ dx = B_x L \eta(y) - \Phi_\perp \frac{y}{W} \\
& + B_x \int_0^y [\eta(L/2, \tilde{y}) - \eta(-L/2, \tilde{y})] d\tilde{y} \tag{36}
\end{align*}
\]

assuming \(B_x = 0\).

In order to apply eq. (32) to the case of rippled graphene with vector potential given by eq. (4), we need a model of the height distribution \(\eta\) of the ripples. From eq. (36) we find that it is reasonable to categorize ripples into short ripples and long ripples, depending on whether the wavelength is shorter or longer than \(2L\). Ripples with wavelength shorter than \(2L\) will have a smaller contribution to \(\eta\) in eq. (36) since the integrand oscillates between positive and negative values. For this reason, short ripples will contribute less to interference effects than long ripples with the same amplitude. On the other hand, faster variations in the \(y\)-direction gives a larger magnetic field component perpendicular to the graphene surface, and therefore a larger depairing effect. Short ripples are therefore expected to lead to larger deviations from the analytical approximation given by eq. (32). In particular, they are expected to cause a faster decay, which, as we will see, is also what happens.

In general, the height distribution will be a superposition of long and short ripples. We look first at only long ripples, then at only short ripples and finally at the combination of both short and long ripples. In order to simplify the presentation and analysis, we present solutions for height distributions that can be written as product of cosines. We obtain qualitatively similar result for more realistic, randomized height distributions.
FIG. 3: Critical current $I_c$ for various in-plane magnetic field strengths $B_y$ and out-of-plane magnetic fluxes $\Phi_\perp$ for the height distribution given by eq. (39) with $n = 1$ and $m = 2$. Here, $I_0 = N_0 \varepsilon W D^2/L^3$, $W = 10L_s$, $L = 10\xi = 400$ nm, $\eta_0 = 1$ nm, $\delta/\Delta = 0.02$ and $B_x = 0$. Figure a) shows the analytical solution of $I_c$ against $B_y$ for $\Phi_\perp = 0$ (blue line), compared to the numerical solution (red dots). b) shows analytical solution of $I_c$ against $\Phi_\parallel$ for $B_y = 5$ T and c) shows a logarithmically scaled color plot of analytical $I_c$ where white means zero current and deep blue corresponds to large current.

To model $n$ uniform ripples in the $x$-direction and $m$ uniform ripples in the $y$-direction, we use the height distribution

$$\eta(x, y) = \frac{\eta_0}{2} \cos\left(n\pi \frac{x}{L}\right) \cos\left(m\pi \frac{y}{W}\right),$$

(39)

where $\eta_0$ is the peak-to-peak height difference. Figures 3–5 show the critical current, given by eq. (9), for the height distribution in eq. (39) with $n = 1$ and $m = 2$, $m = 5$ and $m = 10$, respectively. The exchange field, $h$, is set to zero in order to isolate the orbital effect, such that it can be observed whether the orbital effect alone is sufficient to produce roots in the critical current. Physically, the situation with negligible exchange field would be the case if the Thouless energy, $\varepsilon_t$, is much larger than the Zeeman splitting $\mu_B B_y$, where $\mu_B$ is the Bohr magneton.

It can be seen from figs. 3–5 that a height variation of only $1$ nm is sufficient to produce oscillations in the critical current. In particular, the critical current is zero for $\Phi_\perp = 0$ and finite $B_y$ when $m = 2$ and $m = 10$. Both zeros satisfies eq. (38), which is $B_y = 2$ T in this case. We can conclude from this that a zero in the critical current of an SGS junction is not sufficient to identify an exchange-driven $0-\pi$ transition, since zeros can also be produced from the ripples.

Since the junction widths are equal in figs. 3–5, larger $m$ means a larger orthogonal component from the in-plane magnet field. Consequently, the magnetic field strengths for which the weak field assumption, eq. (18), remains valid is reduced when $m$ increases. This is reflected in the correspondence between the numerical simulations and the analytical predictions.

The color plots in figs. 3–5 c) show that the critical current has especially large maxima at $\Phi_\perp/\Phi_0 = km/2$ for integer $k$.

This is also reflected in figs. 3–5 b), which show that the lobe structure has strong maxima at $\Phi_\perp/\Phi_0 = m/2$. To understand why, note that the orbital part of the current can be written as a Fourier transform. That is,

$$I = C(h) \int_{-W/2}^{W/2} \sin\left(\phi_r - \phi_l + 2\pi \frac{B_y L_\parallel}{\Phi_0} - 2\pi \frac{\Phi_\perp y}{\Phi_0 W}\right) dy$$

$$= C(h) \Im \left\{ e^{i(\phi_r - \phi_l)} \int_{-W/2}^{W/2} \exp\left[2\pi i \left(\frac{B_y L_\parallel}{\Phi_0} - \frac{\Phi_\perp y}{\Phi_0 W}\right)\right] dy \right\},$$

(40)

where $C$ is a function of the exchange field. Hence, the critical current can be written as

$$I_c = C(h) \left\langle \mathcal{F} \left\{ \text{rect}(y/W) e^{2\pi i B_y L_\parallel \Phi_0/\Phi_0} \right\} \left(2\pi \Phi_\perp/\Phi_0 W\right) \right\rangle,$$

(41)

where $\mathcal{F}$ is the rectangular function and $\langle \rangle$ means Fourier transform. Accordingly, a Fourier analysis of the current response to out-of-plane magnetic fields can uncover properties of the ripple structure. In this case, $\tilde{\eta}$ is a cosine with wavenumber $m\pi/W$, so it is reasonable that the Fourier transform peaks at $2\pi \Phi_\perp/\Phi_0 W = km\pi/W$ with strengths that depends on $B_y$.

Figures 3–5 a) also give clues to how the full solution of the Usadel equation deviates from eq. (32) when the magnetic field is strong. Two things seem to happen when the flux density is strong. First, compared to the analytical solution, the full solution decays more rapidly as $B_y$ increases. That the critical current decays faster than the analytical solution predicts is unsurprising, since we neglected the depairing effect of the magnetic field in our derivation of eq. (32).
Second, the functional dependence on \( B_y \) is slower in the numerical case, in the sense that roots and extremal values in the critical current are skewed towards larger values of \( B_y \). A plausible explanation for this phenomenon is that the full solution varies more slowly in the \( y \)-direction compared to the analytical approximation in eq. (23). The analytical solution has \( \partial f \partial y \propto B \), but it neglects the boundary condition that demands \( \partial f \partial y = 0 \) when \( y = \pm W/2 \). Hence, it is possible that the analytical solution overestimates the variation of \( f \) with respect to \( y \), at least close to \( y = \pm W/2 \). The roots in the critical current occur because the magnetic field creates mutually cancelling oscillations in the current density as a function of \( y \). If the analytical approximation overestimates how fast these oscillations occur, it will underestimate the magnetic field required to give \( I_c = 0 \). The faster decay, but slower variation is also exactly what happens in the case of uniform magnetic fields, as can be seen from fig. 3 in Ref. [24].

Moving on to short ripples, fig. 6 shows the critical current for the distribution given by eq. (39) with \( n = 11 \), \( m = 10 \) and \( \eta_0 = 1 \text{ nm} \). With \( L = 400 \text{ nm} \), this corresponds to a ripple length of 40 nm, which is comparable to the short ripples observed in graphene on SiO\(_2\) [20]. The exchange field is again set to 0. What matters for the analytical approximation is the longitudinally averaged height, \( \bar{\eta} \), which in this case is small because of the rapid oscillations. Hence, the analytical approximation predicts very little change in the critical current at \( \Phi_L = 0 \). On the other hand, the orbital depairing effect is quite large because of the short ripples, which is reflected in the decay of the critical current observed in the numerical solution of the full Usadel equation.

Finally, fig. 7 shows the critical current for combinations of short and long ripples, both with and without a non-zero exchange field. The height distribution in this case given by

\[
\eta = 1 \text{ nm} \times \cos\left(2 \pi \frac{y}{W}\right) + A \cos\left(n \pi \frac{x}{L}\right) \cos\left(n \pi \frac{y}{L}\right),
\]

where \( n = 4 \) for “hBN” and “Large” and \( n = 10 \) for “SiO\(_2\)”. The amplitude of the short ripples are \( A = 0.1 \text{ nm} \), \( A = 0.5 \text{ nm} \), \( A = 2 \text{ nm} \) for “hBN”, “SiO\(_2\)” and “Large”, respectively. The values for “SiO\(_2\)” and “hBN” are chosen such that the short ripple sizes correspond to the observed values for SiO\(_2\) and hBN [20]. The values for “Large” are chosen such that amplitudes of the short ripples are twice as large as the long ripples. In this case the orthogonal component of the magnetic field is much too high for the analytical solution to give accurate results.

Since \( n \) is even, the analytical solution given by eq. (32) is equal for the three cases. The only difference is the magnitude of the additional magnetic flux density that comes from the short ripples. As mentioned above, we should expect a faster decay for larger and faster ripples. This is indeed also what we observe from the numerical results in fig. 7. Interestingly, the location of the roots is not substantially altered by the short ripples. Even in the lowermost panels, where the short ripples are twice as large as the long ripples, the roots in the numerical solution occurs not far from the values of \( B_y \) predicted by the analytical solution, even if the amplitude decays much faster.

Long ripples, as we have seen, can give rise to interference effects that produce oscillations and possibly roots in the critical current. Short ripples, on the other hand, increase the magnetic flux density and can lead to a substantial magnetic depairing effect, which manifest as a rapidly decaying critical current. Hence, the combined effect of short and long ripples can yield a rapidly decaying critical current with zeros, much like what one would expect from a ferromagnet undergoing a 0–\( \pi \) transition.

From fig. 7 it can also be observed that the deviation between the analytical and numerical solutions is smaller when the exchange field is non-zero. This is as expected, since neglecting the contribution from \( B \) in eq. (17) is a better approximation.
Notice that eqs. (43) and (44) scales differently with junction length $L$. Therefore, it is more plausible that an observed zero in the critical current correspond to a 0-\(\pi\) transition when the junction is long. Alternatively, one could try to limit the presence of variations in the $y$-direction that are longer than $L$ by making $W \ll L$.

From figs. 3–5 we also observe that the ripples can substantially alter the Fraunhofer lobe structure found when varying $B_\perp$, while fig. 2 shows that the Fraunhofer pattern is unaltered when the effect of ripples is negligible. Hence, investigating how $I_\text{c}$ depend on $B_\perp$ could also be useful when identifying 0-\(\pi\) transitions. As long as the junction width and diffusivity are approximately constant, a 0-\(\pi\) transition will give rise to a vanishing critical current for all values of out-of-plane magnetic flux densities $B_\perp$. If in addition the effect of ripples is small, one should expect that the critical current as a function of $B_\perp$ is a Fraunhofer pattern at any constant value of the in-plane magnetic field $B_\parallel$. Accordingly, determining whether the minima in critical current as a function of $B_\parallel$ and $B_\perp$ are straight lines, as in fig. 2, or curved, as in figs. 3–5, can give clues as to whether ripples are important. If ripples are important, eq. (41) could give insight to their structure.

\section{IV. Conclusion}

We have solved the Usadel equation analytically in the presence of an exchange field and an arbitrary magnetic field distribution, under the assumption of a weak proximity effect and a weak magnetic field. The solution has been applied to SGS-junctions with the combined Zeeman effect and orbital effect coming from an in-plane magnetic field. Deviations from the analytical solution at large magnetic fields have been studied numerically. We find that the orbital effect that results from a curvature in the graphene can produce a critical current response that is similar to what one would get by increasing the exchange field. Slow variations in the graphene height distributions give rise to interference effects that produce oscillations in the critical current, while rapid variations cause larger orbital depairing effects that lead to a faster critical current decay rate.

Since both the Zeeman splitting and orbital effects in rippled graphene can cause similar behaviour, extra care must be taken when identifying possible 0-\(\pi\) transitions. The interference effect from ripples is reduced if the width of the junction is much smaller than the length. In addition to reducing the relative effect of ripples compared to the Zeeman splitting, which is achieved by increasing the length of the junction and minimizing the height variations, it could also be useful to look at how the critical current varies with a perpendicular magnetic field. The effect of ripples, if present, will then typically alter the Fraunhofer pattern observed at zero in-plane magnetic field. Because slow height variations are difficult to detect using surface probe techniques, we suggest the use of parallel magnetic field as a means to probe the presence of such variations.
