Abstract
Atomically strong light pulses can drive sub-optical-cycle dynamics. When the Rabi frequency – the rate of energy exchange between light and matter – exceeds the optical carrier frequency, fascinating non-perturbative strong-field phenomena emerge, such as high-harmonic generation and lightwave transport. Here, we explore a related novel subcycle regime of ultimately strong light-matter interaction without a coherent driving field. We use the vacuum fluctuations of nanoantennas to drive cyclotron resonances of two-dimensional electron gases to vacuum Rabi frequencies exceeding the carrier frequency. Femtosecond photoactivation of a switch element inside the cavity disrupts this ‘deep-strong coupling’ more than an order of magnitude faster than the oscillation cycle of light. The abrupt modification of the vacuum ground state causes spectrally broadband polarisation oscillations confirmed by our quantum model. In the future, this subcycle shaping of hybrid quantum states may trigger cavity-induced quantum chemistry, vacuum-modified transport, or cavity-controlled superconductivity, opening new scenarios for non-adiabatic quantum optics.

Strong-field light-matter interaction is characterised by polarisation dynamics occurring faster than an oscillation cycle of light¹–⁵. Extremely strong electric fields have facilitated carrier-wave Rabi flopping² and non-perturbative, lightwave-driven electron dynamics including high-harmonic generation¹,³–⁵ and subcycle transport³–⁷. Subcycle temporal resolution has been crucial in understanding the underlying physics. An opposing limit has been explored in optical microcavities, where novel states of matter can be created by
dressing electronic excitations with virtual photons. When the corresponding vacuum Rabi frequency $\Omega_R$ (the energy exchange rate between a cavity mode and an electronic resonance) assumes a sizeable fraction of the carrier frequency, $\omega_0$, intriguing cavity quantum electrodynamic (c-QED) effects such as the vacuum Bloch-Siegert shift, modified electronic transport, and cavity-controlled chemical reactions arise. Ongoing efforts to increase the coupling strength have recently opened up the regime of $\Omega_R/\omega_0 > 1$ (refs. 19,21). Such deep-strongly coupled vacua can host exotic quantum effects including giant Lamb shifts, a sizable population of virtual photons, or cavity-mediated superconductivity.

While these studies have focused on equilibrium aspects, subcycle changes of $\Omega_R$ have been predicted to unleash a new field of non-adiabatic cavity light-matter interaction. For instance, a switching-induced transfer of energy into the quantum vacuum is predicted to release the virtual photon population of the correlated ground state, similar to Unruh-Hawking radiation of black holes. Abrupt undressing of the matter excitation also promises new ways of investigating the interaction dynamics of vacuum fields with electron transport, Cooper pair bonding, or molecular reactions. Yet, thus far, switching has been limited to $\Omega_R/\omega_0 \leq 0.1$ (ref. 16). Subcycle control of deep-strong coupling comes with incomparably stricter, yet unresolved challenges of integrating electronic excitations with giant dipole moments and optical switching functionalities into extremely subwavelength cavity mode volumes.

Here, we demonstrate an abrupt undressing of deep-strongly light-matter coupled electrons with $\Omega_R/\omega_0 = 1.3$ within $0.05 \times T_0$, where $T_0 = 2\pi/\omega_0$ is the oscillation period of light, by stripping off the cavity field from an electronic excitation. To this end, femtosecond photodoping of a switch structure deactivates the fundamental cavity mode and reduces the amplitude of the resonator field interacting with an electronic resonance by more than an order of magnitude. The strongly subcycle collapse of $\Omega_R$ and the polariton modes is characterised by pronounced high-frequency polarisation oscillations evolving faster by an order of magnitude than a single oscillation cycle of the lower polariton. Our dynamical quantum model links these signatures to an extremely non-adiabatic interruption of the energy exchange of deep-strongly light-matter coupled modes, which opens a new dimension for future investigations of the dynamics of strongly squeezed quantum vacua.

Design of switchable, deep-strongly coupled vacua

Our structures couple the electric field of a metallic THz resonator to the cyclotron resonance (CR) of two-dimensional, high-mobility electron gases in GaAs quantum wells (QWs) separated by AlGaAs barriers (Fig. 1a; see also Methods). At a temperature of 10 K, a variable magnetic bias oriented perpendicularly to the QW plane leads to Landau quantisation with a tuneable CR frequency, $\nu_c$. The resonators consist of an inductive outer ring and a capacitive gap element (Fig. 1a), which determine the resonance frequencies and spatial shapes of the optical modes. The design of our structures was guided by finite-element frequency-domain calculations (see Methods). In particular, the fundamental LC mode is tailored to concentrate the electric near-field within the central gap region (Figs. 1b-d), optimise its overlap with the polarisation field of the CR, and thereby maximise the
strength of light-matter interaction\(^{19}\). Correspondingly, changes of the near field within the region of maximum overlap – the QW plane – strongly influence \(\Omega\).

We exploit this idea to deactivate light-matter coupling all-optically. To this end, we place an In\(_{0.55}\)Ga\(_{0.45}\)As patch between the capacitive resonator region\(^{29}\) and the QWs (Fig. 1a, white patch; see also Methods). The alloy features a bandgap of 0.73 eV which enables selective excitation of charge carriers by femtosecond switching pulses with a photon energy of 1.03 eV. As a result, a quasi-metallic THz response can be induced exclusively in the patch, causing a subcycle cut-off\(^{30}\) of the electric near-field. Numerical calculations show that a photoexcited plasma with an electron-hole pair density of \(\rho_{\text{switch}} = 3.5 \times 10^{18} \text{ cm}^{-3}\) efficiently expels the near field out of the resonator gap and, thus, deactivates the LC mode (Figs. 1e,f; see also Extended Data Figure 1). In the gap region, the Landau electrons in the QWs are stripped of the vacuum field which drops to less than 5% of its value without excitation (Figs. 1d,f), leading to a collapse of the coupling strength.

We experimentally test our concept with two structures consisting of 3 and 6 QWs, respectively, each doped with a concentration of \(1.75 \times 10^{12} \text{ cm}^{-2}\) electrons per QW and covered with an array of resonators designed for a frequency of the LC mode of \(\nu_{LC} = \frac{\omega_{LC}}{2\pi} = 0.85\) THz (3-QW structure) and 0.5 THz (6 QW structure). Linearly polarised, single-cycle THz transients (Fig. 1a, blue waveform) are focused through the structures and detected electro-optically (see Methods and Extended Data Figure 2). Light-matter coupling leads to dressing of electrons by the vacuum field, which forms new eigenstates called cavity polaritons. In the transmission spectra, these resonances manifest by characteristic minima, whose frequencies depend on the detuning between the LC mode and the CR. We systematically control \(\nu_c\) by varying the magnetic bias field while recording the transmission spectra of the structures.

**Deep-strong coupling and its optical deactivation**

The data for the 3-QW sample (Fig. 2a) clearly exhibit a lower polariton (LP) branch which emerges from the CR at low frequencies, while the upper polariton (UP) resonance is observed at 1.35 THz for \(\nu_c = 0\) THz. As \(\nu_c\) grows, the polariton frequencies increase with opposite curvatures, leading to the characteristic anti-crossing shape. Owing to the extremely strong light-matter coupling, even the minimum spectral separation at the anti-crossing point (\(\nu_c = \nu_{LC}\)) still exceeds the carrier frequency of light; here the LP and UP frequencies are \(\nu_{LP} = 0.48\) THz and \(\nu_{UP} = 1.49\) THz, respectively. Under these conditions, the vacuum ground state is populated by 0.1 virtual photons resulting from the sizable contribution of anti-resonant light-matter exchange. An additional coupled resonance occurs approximately 0.2 THz below the UP branch. Terahertz absorption by the bare CR in uncoupled areas between resonator structures explains the prominent transmission minimum at \(\nu_c\) (red diagonal region). We determine a coupling strength of \(\Omega_R/\omega_{LC} = 0.57\) by diagonalising the corresponding Hamiltonian and adjusting the parameters for best agreement with the experimental spectra (see Methods). Applying the same procedure for the 6-QW structure yields a coupling strength of as much as \(\Omega_R/\omega_{LC} = 1.3\) (Fig. 2c), leading to a ground state population of 0.32 virtual photon pairs and amplitudes of the counter-rotating field components\(^{23}\) that exceed those of the resonant fields.
Next, we excite the switching patch by a near-infrared pump pulse (Fig. 1a, red pulse) with a duration of 70 fs, set to arrive at the sample 2 ps before the maximum of the THz pulse. The switched structure exhibits a fundamentally different transmission spectrum (Fig. 2b) characterized by the complete absence of both polariton resonances. This behaviour evidences a full collapse of $\Omega_R$. At the same time, other spectral features, such as the bare CR, remain mostly unaffected, demonstrating the minimally invasive nature of our switching concept which acts almost exclusively on the ultrastrongly coupled state in the gap region of the resonator. The decreased transmission observed above 1.6 THz can be attributed to a red shift of the dipolar cavity mode (see Methods and Extended Data Figure 1). Similarly, the polariton resonances of the 6-QW structure (Fig. 2c) are fully suppressed after photoexcitation (Fig. 2d). These data represent the first-ever optically induced collapse of deep-strong light-matter coupling.

**Subcycle deactivation dynamics**

Going beyond these quasi steady-state settings, we explore the subcycle dynamics of light-matter decoupling by measuring the instantaneous THz response during switching. To this end, the THz pulse and the switching pulse are shifted with respect to each other by a delay time, $t_D$, and the electro-optic detection is performed at a delay time $t$ relative to the THz pulse (Fig. 3a; see also Methods). For photoexcitation at the THz field crest ($t_D = 0$ ps), a strong pump-induced change, $\Delta E$ (Fig. 3b, red curve), of the transmitted THz field, $E$ (Fig. 3b, black curve), emerges. While the amplitude of $\Delta E$ remains small within the first oscillation half-cycle after switching, it becomes comparable to $E$ during the trailing oscillations ($t > 0.5$ ps), owing to a complete suppression of the narrowband polariton resonances. Figure 3c depicts a systematic scan of $\Delta E$ as a function of $t_D$. Along the downward diagonal, $t = -t_D$, the switching pulse abruptly disrupts light-matter exchange in various phases of the polariton oscillations.

We will show next that the complex temporal structure displayed in Fig. 3c is characteristic of an abrupt, subcycle collapse of $\Omega_R$ and that this extreme limit manifests in modulations of the response function, on time scales much faster even than the oscillation period of the coupled modes themselves. In order to extract a well-defined transmission function of the non-equilibrium system, we transform the transmission data into a different time frame in which $\tau = t + t_D$ represents a constant delay between the switching and the electro-optic gate pulses (Fig. 3a; see also Methods). Keeping $\tau$ constant (Fig. 3c, dashed line) and performing a Fourier transform along $t$ leads to the transmission spectra of Fig. 3d. The evolution of these spectra as a function of $\tau$ traces the transition from the light-matter coupled state to the decoupled state. Most remarkably, both polaritons undergo an intriguing oscillatory subcycle change induced by the switching pulse. For a more detailed view, the solid black curve and circles in Fig. 4a line out the transmission change, $\Delta T$, at the LP resonance. $\Delta T$ displays a short-lived increase for $\tau < 0$ ps and reaches its minimum value near $\tau = 0$ ps. Subsequently, $\Delta T$ steeply increases, exhibits an oscillatory feature at $\tau \approx 0.5$ ps, and eventually converges to its final value. The dynamics of this sub-polariton-cycle transition entail frequency components exceeding $\nu_{LP}$ several times. An even more extreme situation prevails for the 6-QW structure (Extended Data Figure 3), where the transmission at the LP resonance exhibits frequency components exceeding $\nu_{LP}$ by an order of
magnitude. Conversely, switching an empty cavity progresses smoothly (Extended Data Figure 4).

### Subcycle quantum model

A theoretical analysis can unambiguously explain these high-frequency dynamics by an abrupt deactivation of deep-strong light-matter coupling. To this end, we model the coherent THz excitation of the polariton states by a mean-field theory of light-matter interaction including anti-resonant terms and a set of time-dependent parameters that define the cavity modes (see Methods). The effect of the subcycle deactivation of the resonator’s LC mode and the resulting collapse of the overlap of light and matter fields are implemented by a single, time-dependent vacuum Rabi frequency, which is reduced to zero in a time interval set by the duration of our switching pulse of 70 fs (see Methods). The calculations trace the dynamics well (Fig. 4a, red curve), reproducing the initial reduction of the transmission, the subsequent steep rise, and the local reduction between $\tau = 0.5$ ps and 1.1 ps. Deviations for $\tau > 1.5$ ps are likely caused by the dynamics of higher resonator modes not accounted for in our model. Importantly, the theory shows that the oscillations only occur for sufficiently fast switching, whereas long control pulses average out the energy oscillations and lead to a more adiabatic transition (Fig. 4a, black dashed curve). A quantitative match with the experimental data is obtained for switching times between $\tau_{\text{switch}} = 10$ fs and 100 fs (Fig. 4a and Methods). This upper bound of $\tau_{\text{switch}}$ corresponds to a fraction of $\tau_{\text{switch}}/T_{\text{LP}} = 0.02$ (0.05) for our 6-QW (3-QW) structure, where $T_{\text{LP}} = \nu_{\text{LP}}^{-1}$ is the oscillation period of the LP.

These oscillations reflect the internal dynamics of the deep-strongly coupled state. Initially, the THz pulse prepares a coherent polarisation at both polariton frequencies and their counter-propagating wave components. The corresponding anti-resonant interaction terms lead to a complex periodic redistribution of the energies stored in the cavity, $E_{\text{cavity}}$, the electronic excitation, $E_{\text{polarisation}}$, and the coupling mechanism itself, $E_{\text{coupling}}$. When the switching pulse abruptly interrupts this transfer, the subsequent dynamics of the uncoupled cavity and electronic polarisation are defined by the corresponding instantaneous field amplitudes at the time of switching. The rapid oscillations of the coupled fields progressing faster than a single polariton oscillation cycle lead to equally rapid oscillations of the response function as a function of the switching time. Conversely, switching a set of uncoupled resonances or coupled resonances within the rotating-wave approximation entails qualitatively different dynamics (see Supplementary Information), which underpins the role of anti-resonant interaction mechanisms in the deep-strong coupling regime.

For an intuitive picture of the subcycle energy exchange, we follow the dynamics of the microscopic fields for the case where the total energy injected by the THz pulse resides in the LP. This eigenmode is characterized by an out-of-phase oscillation of cavity and matter fields corresponding to an oscillating negative coupling energy (Fig. 4b, red curve). $E_{\text{coupling}}$ reaches the same magnitude as all other energies of the system (see Supplementary Information) and counterbalances the synchronously oscillating $E_{\text{cavity}}$ (Fig. 4b, solid black curve) and $E_{\text{polarisation}}$ (Fig. 4b, dashed black curve). Without switching, the total energy decays exponentially (Fig. 4c, black curve). Here, the coupled gap region of the resonator (Fig. 4d, dashed area) is permeated by the electric near-field (Fig. 4e, blue to green colours),
which interacts strongly with the electronic polarisation in the QWs (red colours). In contrast, if the structure is switched, the switching layer is strongly polarised, and the cavity electric field rapidly collapses (Fig. 4f, black colour). If switching occurs near a local minimum of $E_{\text{coupling}}$ (Fig. 4b, black arrow), the negative energy of the coupling mechanism is removed, leading to a rapid increase of the total energy (Fig. 4c, dotted curve). Subsequently, the uncoupled matter mode continues to oscillate freely with an amplitude surpassing its time-averaged value before switching (Fig. 4f, bright yellow colours). The preparation of this unusual, otherwise inaccessible state is thus a direct result of highly non-adiabatic light-matter decoupling.

In conceptual analogy to this situation of a coherent state prepared by a classical THz field, future experiments may exploit the same mechanism to promote virtual excitations from the incoherent vacuum ground state to real excitations. In combination with recent cutting-edge quantum spectroscopy\textsuperscript{31,32}, this concept could form an excellent table-top laboratory to explore quantum electrodynamical phenomena similar to the Unruh-Hawking radiation of black holes\textsuperscript{28}.

**Perspectives**

Our concept extends subcycle strong-field control of matter to a new arena without strong driving fields and adds time as a new control parameter in deep-strong cavity light-matter coupling. Reshaping light-matter hybrid states faster than a cycle of light revealed a novel class of rapid subcycle oscillations of the optical response function with frequency components exceeding the carrier frequency of light by an order of magnitude. The switch-off of deep-strong coupling may even lead to a transfer of energy out of the coupling mechanism, preparing the system in a state otherwise unattainable by external excitation. Among many exciting future perspectives, our approach may be used to switch tailor-cut response functions of all-optically controlled filters and modulators, at arbitrary speed, and explore non-adiabatic quantum optics. By coupling other select low-energy elementary excitations, such as vibrational modes of molecules or lattice vibrations of Josephson plasmons, one may set out to trigger chemical reactions\textsuperscript{13,14}, optically, without the need of a photocatalyst, and steer ultrafast vacuum-modified transport\textsuperscript{11,12} as well as cavity-mediated phase transitions, such as superconductivity\textsuperscript{24,25}, on demand – none of which require THz illumination or direct matter excitation.

**Methods**

**Sample fabrication**

Our symmetrically doped QWs were fabricated by molecular beam epitaxy on a GaAs substrate, and capped by an In$_{0.55}$Ga$_{0.45}$As layer of a thickness of 100 nm. This InGaAs layer exhibits an energy gap of 0.73 eV and an intentionally defect-rich crystal structure which still exhibits photoconductivity, but does not allow a cyclotron resonance to build up. The InGaAs switching patches of an area of 18 $\mu$m $\times$ 22 $\mu$m were formed by electron-beam lithography and wet-chemical etching. The gold THz resonators were subsequently fabricated on top, whereby their gaps were aligned with the switching patches. In a final
step, we glued the sample onto a sapphire window and removed the GaAs substrate in order to prevent effects from two-photon absorption of the switching pulse in the substrate.

**Design of switchable resonators**

The design of our switchable structures is based on finite-element frequency domain calculations in analogy to ref. 19. The THz resonators are arranged in quadratic unit cells of a length of 60 μm. They feature a capacitive gap element in which the electric field of the fundamental LC mode is enhanced by up to a factor of 8 with respect to the far field (Extended Data Figure 1a). In contrast, the near field of the higher-energy, dipolar mode (DP) is strongly enhanced at the outer perimeter of the resonator (Extended Data Figure 1b), allowing for selective switching of the LC mode by photo-doping of the switching patch underneath the central gap. We apply the Drude model for a charge carrier plasma to calculate the contribution that the photoexcitation adds to the dielectric response of the switching patch. The plasma frequency is given by

\[
\omega_p = \sqrt{\frac{\rho_{\text{switch}} e^2}{\epsilon_0 m_{\text{InGaAs}}}.
\]

Here, \( m_{\text{InGaAs}} = 0.04 \) \( m_e \) denotes the effective mass of conduction band electrons in InGaAs, \( m_e \) is the free electron mass, \( \rho_{\text{switch}} \) is the electron charge carrier density, \( \epsilon_0 \) is the vacuum permittivity, and \( e \) is the elementary charge. In the experiment, we chose an optical fluence of 135 μJ/cm² for the switching pulse, leading to saturation of the switching effect. We thus assume a density of photoexcited carriers of \( \rho_{\text{switch}} = 3.5 \times 10^{18} \text{cm}^{-3} \), corresponding to the total density of states of InGaAs within the bandwidth of our switching pulse. As a result, we obtain a plasma frequency of \( \nu_p = \omega_p / 2\pi = 80 \text{THz} \). The dielectric function of the plasma is then given by

\[
\epsilon_{\text{InGaAs}}(\omega) = \epsilon_{\text{InGaAs}}(\infty) - \frac{\omega_p^2}{\omega^2 + i \omega \tau_s}.
\]

where we chose a scattering time of \( \tau_s = 1 \times 10^{-13} \text{s} \), and a static dielectric constant of \( \epsilon_{\text{InGaAs}}(\infty) = 13.7 \). We verify our switching concept by calculating the equilibrium transmission of the switched resonator based on this dielectric response. While the strong screening of the electric field generally reshapes both modes, the impact on the LC mode is much stronger as compared to the DP mode (Extended Data Figure 1c,d). Correspondingly, the calculated transmission spectra reveal that the LC mode is completely quenched, while the DP mode experiences a red shift of 0.25 THz (Extended Data Figure 1e).

We calculate the response of our deep-strongly coupled structures by extending our model with the gyrotropic response of Landau-quantized electrons in the QWs analogously to the procedure detailed in ref. 19. The calculated equilibrium spectra (see Supplementary Information) are compatible with the experimental data and show a distinct LP resonance. Activating the switching patch, the calculations predict a collapse of the light-matter coupling of the fundamental LC mode, as the LP branch disappears completely (see...
Supplementary Information). Other coupled resonances at frequencies above $\nu_c$ experience a slight spectral shift imposed by the red shift of the DP mode, but remain mostly unaffected otherwise.

**Calculation of the coupling strength**

For coupling strengths approaching or entering the deep-strong coupling regime, the influence of cavity modes at energies above the resonantly coupled LC mode changes the overall spectrum of the coupled system. In our THz resonators, the frequency of the DP mode is approximately twice as large as the frequency of the LC mode. As a result, we observe only a small influence of multi-mode coupling which manifests as additional spectral features in the vicinity of the UP branch (Figs. 2a,c). However, the LP branch remains clearly isolated. We thus determine the coupling strength by applying Hopfield’s model in the usual single-mode approximation\textsuperscript{33}, taking into account the frequencies of the LP and the CR, as a function of $\nu_c$.

**Experimental setup**

The layout of our subcycle spectroscopic setup is detailed in Extended Data Figure 2. Femtosecond near-infrared pulses (centre wavelength, 807 nm; pulse energy, 5.5 mJ, pulse duration, 33 fs) from a titanium-sapphire amplifier laser (repetition rate, 3 kHz) were split by a beam splitter into two branches, which drive an optical parametric amplifier (OPA), and THz generation and detection, respectively. The THz generation beam was sent across a delay line introducing the delay time $t_D$, and subsequently focused into a 110 -cut ZnTe crystal of a thickness of 1 mm to generate single-cycle THz pulses by optical rectification. The THz pulses were focused through the sample before the transmitted waveforms were recollimated and focused onto a ZnTe detector crystal using off-axis parabolic mirrors. A small fraction of the near-infrared power was split off after the first delay line, passed through a second delay line introducing the delay time $t$, and used for electro-optic detection of the THz pulses in the detector crystal using polarisation optics and a pair of balanced photodiodes. The OPA generated the near-infrared switching pulses of a duration of 70 fs (FWHM) and a centre photon energy of 1.03 eV. These pulses were focused onto the sample with a spot diameter of 4 mm (FWHM) for homogeneous excitation. Two mechanical choppers modulated the THz and switching pulses, allowing for differential detection of the pump-induced change of the transmitted THz electric field, $\Delta E(t, t_D)$. The linear conversion between $\Delta E(t, t_D)$ and $\Delta E(t, \tau = t + t_D)$ was performed numerically\textsuperscript{34}. The sample was kept at a temperature of 10 K in a magneto-cryostat with a large numerical aperture.

**Light-matter decoupling dynamics of the 6-QW structure**

Our most strongly coupled structure is based on a 6-fold QW stack with a charge carrier concentration of $1.75 \times 10^{12}$ cm$^{-2}$ per QW, and a THz resonator with capacitive gaps located at the outer perimeter (Extended Data Figure 3a,b). The resulting coupling strength is $\Omega_R/\omega_{1C} = 1.3$. The light-matter decoupling dynamics (Extended Data Figure 3c-e) display qualitatively similar yet more extreme sub-polariton-cycle oscillations as compared to the 3-QW structure (Figs. 3 and 4). In particular, the dynamics include frequencies exceeding the frequency of the LP mode by more than an order of magnitude (Extended Data Figure 3f).

*Note: The text continues with further details and scientific discussions.*
Switching dynamics of an uncoupled THz resonator

As a control experiment, we investigate the switching dynamics of an uncoupled THz resonator identical to the 3-QW structure, yet without quantum wells. The pump-probe THz field as a function of delay time, \( t \), and pump-probe delay time, \( t_D \) (Extended Data Figure 4a) is obtained by performing the same subcycle switching measurement as for the coupled structures. The resulting time-dependent transmission spectra (Extended Data Figure 4b) demonstrate the spectral selectivity of the switching concept which affects mostly the narrowband range of the fundamental LC mode of the resonator at 0.8 THz, and the more broadband DP mode at 1.8 THz. After an initial reduction of the transmission, the switching dynamics of the fundamental mode progresses monotonically (Extended Data Figure 4c, black curve), leading to an overall increase of the transmission by 0.18 after switching. By contrast, the transmission extracted at a frequency of 2.1 THz, for reference, is left mostly unchanged (Extended Data Figure 4c, red curve).

Quantum model of non-adiabatic deactivation dynamics of deep-strong coupling

We theoretically investigate the decoupling dynamics of our structures by a theory developed specifically for our setting, which treats light-matter interaction in the deep-strong coupling regime beyond the rotating-wave approximation, on subcycle time scales. Light-matter coupling is implemented between the LC mode and the Landau-quantized electrons with a vacuum Rabi frequency \( \Omega_R \). While light-matter coupling of the DP mode is neglected, its influence on the transmission and its frequency shift during switching are included in the theory. The Hamiltonian

\[
\hat{H} = \hat{H}_{\text{cavity}} + \hat{H}_{\text{Landau}} + \hat{H}_{\text{int}} + \hat{H}_{\text{dia}} + \hat{H}_{\text{ext}}
\]

accounts for the cavity modes via

\[
\hat{H}_{\text{cavity}} = \sum_j \hbar \omega_j \hat{a}_j^{\dagger} \hat{a}_j
\]

where \( \hat{a}_j \) is the bosonic annihilation operator of the LC (\( j = \text{LC} \)) and DP (\( j = \text{DP} \)) modes. Excitations of the matter mode are implemented assuming a large number of Landau electrons and a weak THz excitation, whereby \( \hat{b} \) is the corresponding bosonic annihilation operator and \( \omega_c \) is the cyclotron resonance frequency,

\[
\hat{H}_{\text{Landau}} = \hbar \omega_c \hat{b}^{\dagger} \hat{b}.
\]

Light-matter interaction is described by the operator

\[
\hat{H}_{\text{int}} = \hbar \Omega_R \left( \hat{a}_{\text{LC}}^{\dagger} \hat{b}^{\dagger} + \hat{b} \right)
\]
and contains both resonant terms as well as anti-resonant contributions proportional to $a_{LC} \hat{b}$ and $a_{LC}^\dagger \hat{b}^\dagger$, which take the dynamics in the deep-strong coupling regime into account. Furthermore, the cavity experiences a blue shift by diamagnetic interactions,

$$\hat{H}_{\text{dia}} = \hbar D (a_{LC} + a_{LC}^\dagger)^2,$$

where $D = \frac{\Omega R^2}{\omega_c}$. Finally, the coupling to the external THz field, $E_{\text{ext}}(t)$, is contained in $\hat{H}_{\text{ext}}$.

We derive the subcycle dynamics of the cavity and matter fields by applying the Heisenberg equation of motion and performing a mean-field treatment, $\alpha_j = \langle a_j \rangle$ and $\beta = \langle \hat{b} \rangle$. The resulting equations of motion read

$$\frac{d}{dt} \alpha_{LC} = -i \omega_{LC} \alpha_{LC} - \gamma_{LC} \alpha_{LC} - i \Omega_R \left[ \beta(t) + \beta^*(t) \right] - 2iD [\alpha_{LC}(t) + \alpha_{LC}^*(t)] + \kappa_{LC} E_{\text{ext}}(t),$$

$$\frac{d}{dt} \alpha_{DP} = -i \omega_{DP} \alpha_{DP} - \gamma_{DP} \alpha_{DP} + \kappa_{DP} E_{\text{ext}}(t),$$

$$\frac{d}{dt} \beta = -i \omega_c \beta - \gamma_c \beta - i \Omega_R \left[ \alpha_{LC}(t) + \alpha_{LC}^*(t) \right],$$

where we introduced damping terms $\gamma_j$ and $\gamma_c$ for the cavity and matter modes, respectively, and scaled each cavity mode’s coupling to the external field by an individual coupling parameter $\kappa_j$.

This set of coupled differential equations models the response of our structure for fixed parameters of the cavity and matter modes. Next, we implement the decoupling mechanism by a time-dependent vacuum Rabi frequency $\Omega_R(t+\tau_D)$, which transitions from its equilibrium value, $\Omega^0_R$, to its value after switching, $\Omega^f_R = 0$, whereby its instantaneous change is proportional to the rate of generation of photoexcited carriers. For the switching pulse, we use a Gaussian temporal shape with a FWHM of $\tau_{\text{switch}}$ and obtain

$$\Omega_R (t + \tau_D) = \frac{\Omega_R^0}{2} \left[ 1 + \sqrt{2\pi} \tau_{\text{switch}} \int_0^{t+\tau_D} e^{-\frac{4\ln 2}{\tau_{\text{switch}}^2} \left( t - \tau_D' \right)} dt \right].$$

We furthermore introduce dynamical dampings, $\gamma_j(t+\tau_D)$, and coupling parameters, $\kappa_j(t+\tau_D)$, for the LC and DP mode. For the LC cavity mode, we reduce the coupling to the external field by 50%. We implement the frequency shift of the DP mode by a corresponding time-dependent value $\omega_{DP}/2\pi$ which is shifted from 2.2 THz to 1.8 THz, while its far-field coupling is increased by 45%. Solving for these dynamics, we obtain the electric field $E(t, \tau_D)$ as a function of $\tau_D$, and the corresponding transmission $\Delta T(\nu, \tau)$ (ref. 34) (Fig. 4).

### Estimation of the light-matter decoupling time

Our light-matter decoupling mechanism is based on the screening of the electric near-field of the fundamental LC mode of the THz resonators by a charge carrier plasma created by
femtosecond excitation with near-infrared optical pulses. The switching pulses of a duration of 70 fs (FWHM) create a carrier density of \( \rho_{\text{switch}} = 3.5 \times 10^{18} \text{ cm}^{-3} \) corresponding to an electron plasma frequency of \( \nu_p = 80 \text{ THz} \). The time for the build-up of screening\(^3\), 
\[ t_c = \frac{1}{\nu_p} = 12.5 \text{fs}, \]
leads us to expect that the near-field is cut off within approximately the duration of the switching pulse.

We verify this estimate by a series of calculations based on our dynamical model, in which we systematically vary \( \tau_{\text{switch}} \) for our 3-QW structure. The calculations show that the amplitude of the oscillatory dynamics matches the experimental data only for \( \tau_{\text{switch}} < 100 \text{ fs} \), which we thus identify as an upper limit of the light-matter decoupling time, compatible with the estimate based on the plasma frequency. Larger values of \( \tau_{\text{switch}} \), on the contrary, lead to a reduction of the oscillation amplitude up to a completely monotonic increase of \( T \) (Fig. 4a, black dashed curve).

**Extended Data**

**Extended Data Fig. 1.** Calculated spatial and spectral characteristics of the resonator structure. 
(a), Enhancement of the amplitude of the right-circularly polarized near-field component, \( E_{\sigma^+} \), of the fundamental LC mode, relative to the far-field amplitude, \( E_0 \), at a depth of \( z = -200 \text{ nm} \), for an undoped switching layer (see Fig. 1). (b), Corresponding near-field enhancement of the dipolar mode. (c), Near-field enhancement with a doped switching layer, for the LC mode, and (d), for the dipolar mode. (e), Transmission spectra for a doped and an undoped switching patch, respectively.
Extended Data Fig. 2. Experimental setup.

The near-infrared (NIR) pulse train (centre wavelength, 807 nm; pulse energy, 5.5 mJ, pulse duration, 33 fs) generated in a titanium-sapphire amplifier (repetition rate, 3 kHz) is split by a beam splitter (BS1) into a first branch driving an optical parametric amplifier (OPA) and a second branch for THz generation and detection. A delay stage (DS1) controls the common delay $t_D$ of THz and electro-optic sampling pulses. A second beam splitter (BS2) picks off the gate pulse which is delayed by a second stage (DS2) controlling the electro-optic sampling delay, $t$. The gate is focused through the detection crystal (C2) by a lens (L1), after which its polarisation state is analysed by corresponding optics ($\lambda/4$, quarter wave plate; WP, Wollaston prism; PD, photodiodes). The NIR power transmitted through BS2 is focused onto the THz generation crystal (C1) by an off-axis parabolic mirror. A wafer (W) transmits only the generated THz waveform. Off-axis parabolic mirrors recollimate and focus the pulses through the sample (S), which is located in the magnet cryostat (MC) and kept at a temperature of 10 K. Here, a magnetic bias ($B$) of up to 5.5 T is applied perpendicular to the sample surface. The transmitted THz waveform is recollimated and focused onto the detector crystal, collinearly with the gate pulse. The NIR signal output from the OPA (centre wavelength, 1200 nm; pulse energy, 17 $\mu$J, pulse duration, 70 fs) is focused by a lens (L2) onto the focal point of the THz pulses on the sample. Mechanical choppers (CH) are placed in the beam paths of THz generation and switching pulses to enable differential detection.
Extended Data Fig. 3. Subcycle switching dynamics of the 6-QW structure with $\Omega_R/\omega_{LC} = 1.3$.

**a**, Enhancement of the right-circularly polarized near-field amplitude, $E_{\sigma^+}$, of the fundamental LC mode relative to the far-field amplitude, $E_0$, at a depth of $z = -200$ nm, for an unexcited switching layer. **b**, Corresponding near-field enhancement with a photoexcited switching layer. **c**, Transmission spectra of the 6-QW structure as a function of pump-probe delay time, $\tau$, at the anti-crossing point. The dashed lines mark the frequency windows of the lower and upper polariton resonances at 0.17 THz and 1.62 THz, respectively. The transmission exhibits oscillatory dynamics at the frequency of **d**, the UP, and **e**, the LP, caused by the non-adiabatic switch-off. **f**, Spectrum of the switching dynamics of the LP of panel **e**. Vertical dashed lines indicate the resonance frequency of the LP, $\nu_{LP}$, and $10 \times \nu_{LP}$, for reference.
Extended Data Fig. 4. Switching dynamics of an uncoupled THz resonator.

a, Pump-probe THz signal during femtosecond photoexcitation. The charge carrier concentration resulting from femtosecond photoexcitation is $3.5 \times 10^{18}$ cm$^{-3}$. b, Corresponding transmission spectra, in the $\tau$-frame. c, Black curve: Differential transmission of the LC mode extracted within the frequency window outlined in panel b by dashed black lines. Red curve: Differential transmission extracted within the frequency window outlined in panel b by dashed white lines, for reference.

Figure 1. Resonator scheme for switchable deep-strong light-matter coupling.

**a.** The light fields of THz resonators (gold shapes) are coupled to the cyclotron resonances (inset) of two-dimensional electron gases (red layers) kept at a temperature of 10 K, and interrogated by THz transients (blue waveform). A switch element (white patch) placed in the area of maximum field enhancement is photoexcited by a near-infrared femtosecond pulse (red shape) to disrupt light-matter coupling. **b.** Calculated enhancement of the right-circularly polarised near-field component $E_{\sigma+}/E_0$, to which the cyclotron resonance selectively couples, whereby $E_0$ is the far-field amplitude. The data are calculated at the resonance frequency of the LP mode. Inset, zoom into the gap region. **c.** Near-field enhancement in the QW plane, 200 nm below the surface. **d.** Near-field enhancement in the QW plane along $y = 0$, without photoexcitation. **e.** The same setting as in c yet with photoexcited charge carriers of a concentration of $\rho_{\text{switch}} = 3.5 \times 10^{18} \text{cm}^{-3}$ in the switching patch, squeezing the LC mode out of the gap region. **f.** Corresponding near-field enhancement in the QW plane along $y = 0$. 
Figure 2. Steady-state transmission $T$ through an array of deep-strongly coupled resonators before and after light-matter decoupling.

a, Spectra of the 3-QW structure as a function of the CR frequency, $\nu_c$. The dashed lines tracing the LP and UP resonances result from a single-mode model of light-matter coupling, and correspond to a normalized coupling strength of $\Omega_R/\omega_{LC} = 0.57$. b, After photoexcitation, the polariton resonances are absent. c, Corresponding transmission spectra of the 6 QW structure with a coupling strength of $\Omega_R/\omega_{LC} = 1.3$ before and d, after photoexcitation.
Figure 3. Non-adiabatic deactivation dynamics of deep-strong coupling.

a. Schematic of excitation. The switching pulse (blue pulse) is shifted with respect to the THz transient (red waveform) by a delay time $t_D$, and electro-optic sampling (EOS) is performed at a delay time $t$ (orange pulse).
b. Transmitted THz transient before excitation (black curve), and pump-probe signal $\Delta E$ for $t_D = 0$ ps (red curve, temporal position of maximum of switching pulse indicated by arrow).
c. $\Delta E$ as a function of the EOS delay time, $t$, and the pump-probe delay time, $t_D$. The grey diagonal line ($t = -t_D$) indicates a constant delay $\tau = t + t_D = 0$ ps (see panel a).
d. Transmission spectra obtained by Fourier transformation of the data in c along lines of constant $\tau$. The dashed lines indicate the FWHM of the polariton resonances centred at a frequency of 0.48 THz and 1.49 THz, respectively.
Figure 4. Sub-polariton-cycle switching oscillations.

a. The differential transmission $\Delta T$ of the LP (black curve and circles) extracted within the highlighted spectral range in Fig. 3d shows distinct oscillations on a time scale of less than a single polariton cycle, as confirmed by our calculation for a switching time of 100 fs (red curve). Dotted and dashed curves: Calculations of $\Delta T$ for switching times of 10 fs, and 800 fs, respectively. The error bar indicates the standard deviation of the experimental signal, multiplied by 5, for better visibility.

b. Energy of the cavity (solid black curve), polarisation (dashed black curve) and coupling mechanism (red curve) when only the LP is excited. The black arrow marks a local extremum of these energies.

c. Decay of the total energy without switching (solid black curve), and for switching when the coupling energy is minimized (dotted black curve).

d. Cut-away view of the structure visualizing the near fields in the principal planes intersecting in the centre of the resonator.

e. Close-up of the central gap region highlighted by the dashed rectangle in d, showing the time-averaged fields right before switching. Red and yellow colours visualize the electric field, while the polarisation of the QW structure is shown in blue and green colours. The vertical size of the QWs is exaggerated for illustration purposes. The switching layer (SL) is indicated by the dashed line.

f. Polarisation shortly after the switch-off of light-matter coupling. The switching layer is strongly polarised. While the electric field of the resonator has collapsed, the electronic polarisation is boosted as compared to its time-averaged value before switching.
