BEC-BCS Crossover in the Nambu–Jona-Lasinio Model of QCD

Gaofeng Sun∗, Lianyi He† and Pengfei Zhuang‡

Physics Department, Tsinghua University, Beijing 100084, China

The BEC-BCS crossover in QCD at finite baryon and isospin chemical potentials is investigated in the Nambu–Jona-Lasinio model. The diquark condensation in two color QCD and the pion condensation in real QCD would undergo a BEC-BCS crossover when the corresponding chemical potential increases. We determined the crossover chemical potential as well as the BEC and BCS regions. The crossover is not triggered by increasing the strength of attractive interaction among quarks but driven by changing the charge density. The chiral symmetry restoration at finite temperature and density plays an important role in the BEC-BCS crossover. For real QCD, strong couplings in diquark and vector meson channels can induce a diquark BEC-BCS crossover in color superconductor, and in the BEC region the chromomagnetic instability is fully cured and the ground state is a uniform phase.

I. INTRODUCTION

There exists a rich phase structure of Quantum Chromodynamics (QCD), for instance, the deconfinement process from hadron gas to quark-gluon plasma and the transition from chiral symmetry breaking to the symmetry restoration at high temperature and/or baryon density, the color superconductivity at low temperature but high baryon density, and the pion superfluidity at low temperature but high isospin density. The physical motivation to study the QCD phase diagram is closely related to the investigation of the early universe, compact stars and relativistic heavy ion collisions.

While the perturbation theory of QCD can well describe the properties of the new phases at high temperature and/or high density, the study on the phase transitions themselves at moderate temperature and density depends on lattice QCD calculation and effective models with QCD symmetries. While there is not yet precise lattice result for real QCD at finite baryon density due to the fermion sign problem, it is in principle no problem to do lattice simulation for two color QCD at finite baryon density and real QCD at finite isospin density. The QCD phase transitions at finite baryon and/or isospin chemical potential are also investigated in many low energy effective models, such as chiral perturbation theory, linear sigma model, Nambu–Jona-Lasinio model, random matrix model, ladder QCD, strong coupling lattice QCD, and global color model.

It is generally expected that there would exist a crossover from Bose-Einstein condensation for diquarks at finite baryon density and pions at finite isospin density. In the chemical potential region above but close to the critical value \( \mu_c \) for diquark condensate in two color QCD or pion condensate in real QCD, since the deconfinement does not yet happen, the system should be in the BEC state of diquarks or pions. On the other hand, at a sufficiently high chemical potential \( \mu >> \mu_c \), the ground state of the system becomes a BCS superfluid where quark-quark or quark-antiquark Cooper pairs are condensed. Therefore, there should be a crossover from BEC state to BCS state when the chemical potential or density increases. The BEC-BCS crossover, which is a hot topic in and beyond condensed matter and ultracold fermion gas, was recently extended to relativistic fermion superfluid by increasing the attractive coupling among fermions. However, this is not the only way to trigger BEC-BCS crossover. In this paper, we will study the BEC-BCS crossover induced by density effect and chiral symmetry restoration. This density induced BEC-BCS crossover is like the one found in nuclear matter and non-dilute fermi gas.

The features of BEC-BCS crossover have been widely discussed in condensed matter and ultracold fermion gas. We list here only the essential characteristics:

1) There exist two important temperatures, one is the phase transition temperature \( T_c \) for the superfluid at which the order parameter vanishes, and the other is the molecule dissociation temperature \( T^* \). In the BCS limit, there exists no stable molecule, and \( T^* \) approaches to \( T_c \). In the BEC limit, all fermions form stable dimer molecules, and \( T^* \) becomes much larger than \( T_c \).

2) The chemical potential is equal to the Fermi energy of non-interacting fermion gas in the BCS limit but becomes negative in the BEC region. In the BEC limit, the absolute value of the chemical potential tends to be half of the molecular binding energy. This is true both near the critical temperature and in the superfluid ground state.

3) The fermion momentum distribution changes significantly when we go from the BCS to BEC. In the BEC
limit, the distribution near the Fermi surface is still very sharp and similar to the one in non-interacting fermion gas. However, it becomes very smooth in the whole momentum space in the BEC limit.

To be specific, we express the typical dispersion of fermion excitations in a superfluid as

$$E_p = \sqrt{(\xi_p - \mu)^2 + \Delta^2},$$

where $\Delta$ is the superfluid order parameter. In non-relativistic homogeneous system, we have $\xi_p = p^2/(2m)$. In the BCS case, we have $\mu > 0$, the minimum of the dispersion is located at nonzero momentum $|p| = \sqrt{2m\mu}$ and the excitation gap is $\Delta$. However, when $\mu$ becomes negative in the BEC region, the excitation gap becomes $\sqrt{\mu^2 + \Delta^2}$ rather than $\Delta$ itself, and the minimum of the dispersion is located at $|p| = 0$. This can be regarded as the definition of a BEC-BCS crossover at zero temperature.

How can we extend this definition to relativistic systems? In relativistic case, we have $\xi_p = \sqrt{\vec{P}^2 + m^2}$. In comparison with the non-relativistic result, we should define a new chemical potential $\mu_N = \mu - m$. For $\mu > m$, we have $\mu_N > 0$, the minimum of the dispersion is located at nonzero momentum $|p| = \sqrt{\mu^2 - m^2}$ and the excitation gap is $\Delta$. On the other hand, for $\mu < m$, $\mu_N$ becomes negative, the excitation gap becomes $\sqrt{\mu_N^2 + \Delta^2}$ and the minimum of the dispersion is located at $|p| = 0$. This analysis indicates that the BEC-BCS crossover in relativistic fermion gas is controlled by $\mu_N = \mu - m$ rather than the chemical potential $\mu$ itself. An interesting phenomenon then arises: The BEC-BCS crossover would happen when the fermion mass $m$ varies in the process of chiral symmetry restoration at finite temperature and density.

The effective models at the hadron level can only describe the BEC state of hadrons and diquarks, they cannot describe the possible BEC-BCS crossover when the chemical potential increases. One of the effective models that enables us to describe quark and meson properties is the Nambu–Jona-Lasinio (NJL) model applied to quarks and diquark condensation at finite baryon chemical potential ($T - \mu_B$) plane calculated in the model is very close to the one obtained from lattice QCD. It is natural to extend the NJL model to studying diquark condensation at finite baryon chemical potential and pion condensation at finite isospin chemical potential. While there is no reliable lattice result for real QCD with diquark condensation at finite baryon chemical potential, the calculation of diquark condensation in the NJL model agrees well with the lattice simulation of two color QCD. Also, the NJL model calculation of pion superfluidity agrees well with the lattice simulation of real QCD at finite isospin chemical potential. It is natural to ask: How can such a model with quarks as elementary blocks describe the BEC-BCS crossover of diquarks and pions? In non-relativistic fermion gas, the microscopic model with four-fermion interaction can describe well the BEC-BCS crossover at least at zero temperature. Motivated by this fact, we believe that the NJL model should describe well the BEC-BCS crossover in QCD at finite density.

The paper is organized as follows. In section II we investigate the diquark BEC-BCS crossover at finite baryon chemical potential in the NJL model of two color QCD. The possible diquark BEC-BCS crossover in real QCD is investigated in the NJL model in section III. In section IV we study the BEC-BCS crossover of pion condensation at finite isospin chemical potential. We summarize in section V.

II. DIQUARK BEC-BCS CROSSOVER IN TWO COLOR NJL MODEL

Let us first consider the diquark condensation in two color QCD. The advantage to take two color QCD is that the diquarks in this case are colorless baryons and the diquark condensation breaks the baryon symmetry $\text{U}_B(1)$ rather than the color symmetry $\text{SU}_c(2)$. The confinement in two color QCD is less important than in three color QCD. We start with the two color and two flavor NJL model

$$\mathcal{L} = \bar{\psi}(i\gamma^\mu\partial_\mu - m_0)\psi + G_s \left[ (\bar{\psi}\psi)^2 + (\bar{\psi}\gamma_5\tau\psi)^2 \right] + G_d (\bar{\psi}\gamma_5\tau_2\tau C\bar{\psi}^T)(\psi^T C\gamma_5\tau_2 t_2\psi),$$

where $m_0$ is the current quark mass, $\tau$ and $t_2$ are the Pauli matrices in flavor and color spaces, and the two coupling constants $G_s$ and $G_d$ are connected by a Fierz transformation in color space, which is called Pauli-Guerry symmetry and connects quarks and anti-quarks. As a consequence, diquarks are color singlet baryons and diquarks and pions become degenerate.

The key quantity describing a thermodynamic system is the partition function $Z$ which can be expressed as

$$Z = \int [d\bar{\Psi}] [d\Psi] e^{\int_0^\beta d\tau \int d^4x (\mathcal{L} + \frac{\beta}{4} \bar{\Psi}\gamma_0 \Psi)}$$

in the imaginary time formulism of finite temperature field theory, where the baryon chemical potential $\mu_B$ is introduced explicitly, and $\beta$ is the inverse temperature, $\beta = 1/T$. Using the Hubbard-Stratonovich transformation, we introduce the auxiliary meson fields $\sigma = -2G\bar{\psi}\psi$, $\pi = -2G\bar{\psi}\gamma_5\tau \psi$ and diquark field $\phi = -2G\bar{\psi}^T C\gamma_5\tau_2 t_2\psi$, and the partition function can be written as

$$Z = \int [d\bar{\Psi}] [d\Psi] [d\sigma] [d\pi] [d\phi] [d\phi^*] e^{\int_0^\beta d\tau \int d^4x L_{\text{eff}}},$$

with the effective Lagrangian

$$L_{\text{eff}} = \frac{1}{2} \bar{\Psi} K[\sigma, \pi, \phi] \Psi - \frac{\sigma^2 + \pi^2 + |\phi|^2}{4G},$$

where $K[\sigma, \pi, \phi]$ is a function of $\sigma$, $\pi$, and $\phi$. The effective Lagrangian describes the BEC-BCS crossover of diquarks and pions at finite temperature and baryon chemical potential.
where we have introduced the Nambu-Gorkov spinors
\[ \Psi = \begin{pmatrix} \psi \\ C_\sigma^\dagger \end{pmatrix}, \quad \Psi = \begin{pmatrix} \bar{\psi} & \psi^T C \end{pmatrix}, \]
and the kernel \( K \) is defined as
\[ K[\sigma, \pi, \phi] = \left( \begin{array}{cc} M_+ & i\gamma_5 \phi \gamma_2 t_2 \\ i\gamma_5 \phi^* \gamma_2 t_2 & M_- \end{array} \right) \]
with \( M_\pm = i\gamma_\mu \partial_\mu - m_0 \pm \mu_B \gamma_0 / 2 - (\sigma \pm i\gamma_5 \cdot \pi) \). Integrating out the quark degrees of freedom, we obtain
\[ Z = \int [d\tau][d\pi][d\phi][d\phi^*] e^{-S_{\text{eff}}[\sigma, \pi, \phi]} \]
with the bosonic effective action
\[ S_{\text{eff}}[\sigma, \pi, \phi] = \int_0^\beta d\tau \int d^3x \frac{\sigma^2 + \pi^2 + |\phi|^2}{4G} \]
\[ - \frac{1}{2} \text{Tr} \ln K[\sigma, \pi, \phi], \]
\[ (9) \]

**A. Diquark Fluctuation at \( T > T_c \)**

The diquarks would be condensed when the baryon chemical potential \( \mu_B \) is larger than their mass \( m_d = m_\pi \). In this subsection we focus on the region above the critical temperature \( T_c \) where the diquark condensate vanishes.

After a field shift \( \sigma \to \langle \sigma \rangle + \sigma \) with \( \langle \sigma \rangle = -2G \langle \bar{\psi} \psi \rangle \), the effective action \( S^{(0)}_{\text{eff}} \) at zeroth order in meson and diquark fields gives the mean field thermodynamic potential \( \Omega \),
\[ \Omega = \frac{1}{\beta V} S^{(0)}_{\text{eff}} = \frac{(m - m_0)^2}{4G} + \frac{1}{2\beta V} \ln \det S^{-1}, \]
\[ (10) \]
where \( m = m_0 + \langle \sigma \rangle \) is the effective quark mass, and \( S \) is the quark propagator at mean field level
\[ S = \left( \gamma^\mu \partial_\mu - m + \frac{\mu_B}{2} \gamma_0 \sigma_3 \right)^{-1} \]
\[ (11) \]
with \( \sigma_i \) being the Pauli matrices in the Nambu-Gorkov space. The quadratic term of the effective action reads
\[ S^{(2)}_{\text{eff}}[\sigma, \pi, \phi] = \int_0^\beta d\tau \int d^3x \frac{\sigma^2 + \pi^2 + |\phi|^2}{4G} \]
\[ + \frac{1}{4} \text{Tr} \{ \Sigma[\sigma, \pi, \phi] \Sigma[\sigma, \pi, \phi] \}, \]
\[ (12) \]
where \( \Sigma \) is defined as
\[ \Sigma[\sigma, \pi, \phi] = \begin{pmatrix} \sigma + i\gamma_5 \cdot \pi & i\gamma_5 \phi \gamma_2 t_2 \\ i\gamma_5 \phi^* \gamma_2 t_2 & \sigma - i\gamma_5 \cdot \pi \end{pmatrix}, \]
\[ (13) \]
In momentum space, the second order effective action can be expressed as
\[ S^{(2)}_{\text{eff}}[\sigma, \pi, \phi] = \frac{1}{2} \sum_k \left[ \frac{1}{2G} - \Pi_\sigma(k) \right] \sigma(-k)\sigma(k) \]
\[ + \frac{1}{2G} - \Pi_\pi(k) \pi(-k) \cdot \pi(k) \]
\[ + \frac{1}{2G} - \Pi_\phi(k) \phi(-k) \phi(k) \]
\[ + \frac{1}{2G} - \Pi_\phi(k) \phi(-k) \phi^*(k) \], \]
\[ (14) \]
where \( k = (k_0, \mathbf{k}) \) with \( k_0 = i\omega_n = 2\sin\pi T(n = 0, \pm 1, \pm 2, \ldots) \) is the meson or diquark four momentum, and \( \sum_k = i\tau \sum_n \int d^3k/(2\pi)^3 \) indicates integration over the three momentum \( \mathbf{k} \) and summation over the frequency \( \omega_n \). The polarization functions for the mesons, diquark and anti-diquark can be evaluated as
\[ \Pi_\sigma(k) = 2\Pi_1(k; \mu_B), \quad \Pi_\pi(k) = 2\Pi_2(k; \mu_B), \]
\[ \Pi_\phi(k) = 2\Pi_3(k; \mu_B), \quad \Pi_\phi(k) = 2\Pi_4(k; \mu_B) \]
\[ (15) \]
with the functions \( \Pi_{1,2,3,4}(k; \mu) \) listed in Appendix A.

Without loss of generality, we consider the case \( \mu_B > 0 \). The transition temperature \( T_c \) for the diquark condensation is determined by the well-known Thouless criterion
\[ 1 - 2\Pi_\phi(k = 0) \bigg|_{T = T_c} = 0 \]
\[ (16) \]
together with the gap equation for the effective quark mass derived from the first order derivative of the thermodynamic potential,
\[ \frac{m - m_0}{16Gm} = \int \frac{d^3p}{(2\pi)^3} \frac{1 - f (E_p^+) - f (E_p^-)}{E_p} \bigg|_{T = T_c} \]
\[ (17) \]
with the particle energies \( E_p = \sqrt{p^2 + m^2} \) and \( E_p^\pm = E_p \pm \mu_B / 2 \).

The NJL model is non-renormalizable, a proper regularization is needed to avoid ultraviolet divergence. For instance, one can add a form factor in the above momentum integrations. Since our goal is to study the BEC-BCS crossover which happens far away from the asymptotic region, we employ, for the sake of simplicity, a hard three momentum cutoff \( \Lambda \) to regularize the above equations. In the following numerical calculations, we take the current quark mass \( m_0 = 5 \text{ MeV} \), the coupling constant \( G = 1.5 \times 4.93 \text{ GeV}^{-2} \) and the cutoff \( \Lambda = 653 \text{ MeV} \) to fit the pion mass \( m_\pi = 134 \text{ MeV} \), the pion decay constant \( f_\pi = 93 \text{ MeV} \) and the constituent quark mass \( m = 300 \text{ MeV} \) in the vacuum.

The critical temperature as a function of baryon chemical potential is shown in Fig[1]. The diquark condensed phase starts at \( \mu_B = m_\pi \) and the critical temperature increases with \( \mu_B \) until a saturation value which is about the critical temperature for chiral symmetry restoration at \( \mu_B = 0, T_0 = 185 \text{ MeV} \). At moderate baryon chemical
potential, the critical temperature can be well described by
\[ T_c = T_0 \sqrt{1 - \left(\frac{m_\pi}{\mu_B}\right)^4}. \] (18)

We discuss now the mesons and diquarks above \( T_c \).

The energy dispersions of the mesons and diquarks are
defined by the poles of their propagators,
\[ 1 - 2G_{\Pi_i}(\omega(k),k) = 0, \quad i = \sigma, \pi, d, \bar{d}. \] (19)

While the full dispersion laws can be obtained numerically, we are interested here only in the meson and diquark masses. For \( \sigma \) and \( \pi \), they do not carry baryon number, and their masses are defined as \( m_\sigma = \omega_\sigma(0) \) and \( m_\pi = \omega_\pi(0) \). However, diquarks and anti-diquarks carry baryon numbers and their masses are not exactly their dispersions at \( k = 0 \). To define a proper diquark or anti-diquark mass, we should subtract the corresponding baryon chemical potential from the dispersion, \( m_d = \omega_d(0) + \mu_B \) and \( m_{\bar{d}} = \omega_{\bar{d}}(0) - \mu_B \). For \( \mu_B > 0 \), by comparing equation (16) for the transition temperature \( T_c \) with the above definition of diquark mass, the diquark mass at \( T_c \) is equal to the baryon chemical potential,
\[ m_d(T_c) = \mu_B, \] (20)

which is consistent with the physical picture of relativistic BEC in boson field theory. In Fig.2 we show the meson and diquark mass spectrum above the critical temperature for \( \mu_B < m_\pi \) and \( \mu_B > m_\pi \). For \( \mu_B < m_\pi \), the meson mass spectrum is similar to the case at \( \mu_B = 0 \), but the diquark mass is slightly different from the anti-diquark mass at high temperature. For \( \mu_B > m_\pi \), the mass spectrum starts at \( T_c \) where the diquark mass is exactly equal to \( \mu_B \). For any \( \mu_B \), we found that the meson or diquark mass becomes divergent at a limit temperature \( T^* \) which indicates the dissociation of the meson or diquark resonances. For small baryon chemical potential, this dissociation temperature is about two times the critical temperature for chiral symmetry restoration, which is consistent with the results in [61]. With increasing baryon chemical potential, while the dissociation temperature for diquarks and mesons decreases, the one for anti-diquarks increases. Since the diquarks are condensed at positive \( \mu_B \), the baryon chemical potential dependence of the diquark dissociation temperature indicates a crossover from diquark BEC to BCS superfluidity. In Fig.3 we show the superfluid transition temperature \( T_c \) and the dissociation temperature \( T^* \) for mesons, diquarks and anti-diquarks. Any \( T^* \) is much larger than \( T_c \) at small \( \mu_B \), but for mesons and diquarks the two temperatures tend to coincide with each other at sufficiently large \( \mu_B \).

![FIG. 1: The superfluid phase transition temperature \( T_c \) scaled by \( T_0 \) as a function of baryon chemical potential \( \mu_B \) scaled by \( m_\pi \).](image1)

![FIG. 2: The meson and diquark masses as functions of temperature for \( \mu_B = 0.06 \) GeV and 0.2 GeV.](image2)

![FIG. 3: The meson and diquark dissociation temperatures as functions of the baryon chemical potential.](image3)
To investigate the diquark excitation in detail, we consider the diquark spectral function

\[ \rho(\omega, k) = -2\text{Im}D_R(\omega, k), \]  

(21)

where \( D_R(\omega, k) \equiv D(\omega + i\eta, k) \) is the analytical continuation of the diquark Green function \( D(i\omega_n, k) \) defined as

\[ D(i\omega_n, k) = \frac{2G}{1 - 2G\Pi_i(i\omega_n, k)}. \]  

(22)

The spectral function \( \rho \) can be rewritten as

\[ \rho(\omega, k) = \frac{-8G^2\text{Im}\Pi_d(\omega + i\eta, k)}{[1 - 2G\text{Re}\Pi_d(\omega + i\eta, k)]^2 + [2\text{Im}\Pi_d(\omega + i\eta, k)]^2}. \]

At zero momentum \( k = 0 \), the real and imaginary parts of the diquark polarization function can be evaluated as

\[ \text{Re}\Pi_d(\omega + i\eta, 0) = -8 \int \frac{d^3p}{(2\pi)^3} \left[ \frac{1 - 2f(E_p^-)}{\omega - 2E_p + \mu_B} - \frac{1 - 2f(E_p^+)}{\omega + 2E_p + \mu_B} \right], \]

\[ \text{Im}\Pi_d(\omega + i\eta, 0) = -8\pi \int \frac{d^3p}{(2\pi)^3} \left[ (1 - 2f(E_p^-))\delta(\omega - 2E_p + \mu_B) \right. \]

\[ - (1 - 2f(E_p^+))\delta(\omega + 2E_p + \mu_B) \]

\[ = \frac{2}{\pi} \left[ p_\omega E_{p_\omega} \left( 1 - 2f(E_{p_\omega}^-) \right) \Theta(\omega + \mu_B - 2m), \right. \]

with

\[ p_\omega = \sqrt{\left( \frac{\omega + \mu_B}{2} \right)^2 - m^2}. \]  

(25)

For \( \mu_B < 2m \), a diquark can decay into two quarks only when its energy satisfies \( \omega > 2m - \mu_B \), due to the step function \( \Theta \) in the imaginary part. However, for \( \mu_B > 2m \), a diquark can decay into two quarks at any energy and hence becomes an unstable resonance. In Fig. 4, we show the diquark spectral function at zero momentum for several values of baryon chemical potential near the critical temperature \( T_c \). For small baryon chemical potential \( \mu_B < 2m \), the diquarks are in stable bound state at small energy \( \omega < 2m - \mu_B \) and in unstable resonant state at large \( \omega > 2m - \mu_B \). For large baryon chemical potential \( \mu_B > 2m \), the diquarks are impossible to stay in bound state. With increasing baryon chemical potential, the diquarks become more and more unstable and finally disappear. This naturally supports the picture of diquark BEC-BCS crossover.

To understand more clearly the crossover from diquark BEC to BCS superfluidity, we come back to the BEC-BCS crossover in non-relativistic condensed matter physics. A signal of the crossover is that in the BEC region the chemical potential becomes negative and its absolute value tends to be half of the molecule binding energy. Therefore, the fermions are heavy and hard to be excited even at finite temperature, and only molecules survive and condense in the BEC region. In relativistic systems, we should subtract the fermion mass from the chemical potential in order to compare with the non-relativistic result. For this purpose, we define a new chemical potential

\[ \mu_N = \frac{\mu_B}{2} - m. \]  

(26)

In the deep BCS limit with \( \mu_B \to \infty \), we have \( m \to 0 \) and \( \mu_N \to \mu_B/2 \), but in the deep BEC limit with \( \mu_B \to m_\pi \), \( m \) tends to be its vacuum value, and \( \mu_N \) becomes neg-
ative and its absolute value approaches to half of the
diquark binding energy \( \varepsilon_b = 2m - m_+ \). In Fig.5 we show
the effective quark mass \( m \) and the chemical potential
\( \mu_N \) at the critical temperature. The effective quark mass
decreases gradually from its vacuum value to zero with
increasing baryon chemical potential. Since the lowest
quark excitation energy is \( \sqrt{p^2 + m^2} - \mu_B/2 \), the quarks are
hard to be excited near the critical temperature if \( m \)
is much larger than \( \mu_B/2 \). Obviously, at small \( \mu_B \), the
diquarks are easy to be excited near \( T_c \). This means that
even though the elementary blocks of the NJL model are
quarks, the true physical picture at small baryon chemical
potential is the BEC of diquarks. The baryon chemical
potential \( \mu_B^0 \) corresponding to the crossover can be
declared as \( \mu_B = 2m \) which is just the point where the
diquarks become unstable resonances. From Fig.5 \( \mu_B^0 \) is
about 240 MeV. We will give an analytical expression for
\( \mu_B^0 \) in the next subsection.

**B. Diquark Condensation at \( T < T_c \)**

In this section we focus on the quark and diquark be-
behavior in the superfluid phase. We start from the effec-
tive action (9). Since diquarks are condensed, we should
go on not only the chiral condensate \( \langle \sigma \rangle \) but also the
diquark condensates,

\[
\langle \phi^* \rangle = \frac{\Delta}{\sqrt{2}} e^{i\theta}, \quad \langle \phi \rangle = \frac{\Delta}{\sqrt{2}} e^{-i\theta}.
\]  

(27)

A nonzero diquark condensate \( \Delta \neq 0 \) means spontaneous
breaking of \( U_B(1) \) baryon number symmetry in the two
color QCD. The phase factor \( \theta \) indicates the direction of
the \( U_B(1) \) symmetry breaking. For a homogeneous
superfluid, we can choose \( \theta = 0 \) without loss of gener-
ality. A gapless Goldstone boson will appear, which can
be identified as the quantum fluctuation in the phase di-
rection. This Goldstone boson is just the Bogoliubov
phonon in the superfluid.

After a field shift \( \sigma \to \langle \sigma \rangle + \sigma \) and \( \phi \to \Delta + \phi \), the
effective action at zeroth order in meson and diquark
fields gives the mean field thermodynamic potential

\[
\Omega = \frac{1}{\beta V} S_{\text{eff}}^{(0)} = \frac{(m-m_0)^2}{4G} + \frac{1}{2\beta V} \ln \det S_{\Delta}^{-1},
\]  

(28)

where \( S_{\Delta} \) is the mean field quark propagator in the
superfluid phase. In momentum space it can be evaluated as

\[
S_{\Delta}(p) = \left( \gamma^\mu p_\mu - m + \frac{\mu_B}{2} \gamma_0 \gamma_3 + i \gamma_5 \Delta \tau_2 \tau_3 \right)^{-1}
\]  

(29)

with the quark four momentum \( p = (i\nu_n, p) = ((2n+1)i\pi T, p) \) \((n = 0, \pm 1, \pm 2, \cdots)\). In the Nambu-Gorkov
space, it can be explicitly expressed as a matrix

\[
S_{\Delta}(p) = \begin{pmatrix} S_{11}(p) & S_{12}(p) \\ S_{21}(p) & S_{22}(p) \end{pmatrix}
\]  

(30)

with the elements

\[
\begin{align*}
S_{11} &= \frac{(i\nu_n + E_p^-)}{(i\nu_n)^2 - (E_p^-)^2} \Lambda_+ + \frac{(i\nu_n - E_p^+)}{(i\nu_n)^2 - (E_p^+)^2} \Lambda_-, \\
S_{12} &= \frac{(i\nu_n - E_p^-)}{(i\nu_n)^2 - (E_p^-)^2} \Lambda_+ + \frac{(i\nu_n + E_p^+)}{(i\nu_n)^2 - (E_p^+)^2} \Lambda_-, \\
S_{21} &= \frac{-i\Delta \tau_2 \tau_3 \Lambda_+ \gamma_5}{(i\nu_n)^2 - (E_p^-)^2} + \frac{-i\Delta \tau_2 \tau_3 \Lambda_- \gamma_5}{(i\nu_n)^2 - (E_p^+)^2}, \\
S_{22} &= \frac{-i\Delta \tau_2 \tau_3 \Lambda_- \gamma_5}{(i\nu_n)^2 - (E_p^-)^2} + \frac{-i\Delta \tau_2 \tau_3 \Lambda_+ \gamma_5}{(i\nu_n)^2 - (E_p^+)^2},
\end{align*}
\]

(31)

where \( \Lambda_\pm \) are the energy projectors

\[
\Lambda_\pm(p) = \frac{1}{2} \left[ 1 \pm \frac{\gamma \cdot (\eta \cdot p + m)}{E_p} \right],
\]  

(32)

and \( E_p^\pm = \sqrt{(E_p^\pm)^2 + \Delta^2} \) are quark energies in the
superfluid phase. The momentum distributions of quarks
and anti-quarks can be calculated from the positive and
negative energy components of the diagonal propagators
\( S_{11} \) and \( S_{22} \),

\[
\begin{align*}
n_q(p) &= \sum_n \frac{i\nu_n + E_p^-}{(i\nu_n)^2 - (E_p^-)^2} e^{i\nu_n \eta} = \frac{1}{2} \left( 1 - \frac{E_p^-}{E_\Delta} \right), \\
n_{\bar{q}}(p) &= \sum_n \frac{i\nu_n + E_p^+}{(i\nu_n)^2 - (E_p^+)^2} e^{i\nu_n \eta} = \frac{1}{2} \left( 1 - \frac{E_p^+}{E_\Delta} \right).
\end{align*}
\]  

(33)

It has been demonstrated in non-relativistic models
that the BCS mean field theory can describe well the
BEC-BCS crossover at low temperature, \( T \ll T_c \). Here
we will treat the ground state in the mean field ap-
nproximation. The gap equations to determine the effective
quark mass \( m \) and diquark condensate \( \Delta \) can be obtained
by the minimum of the thermodynamic potential,

\[
\frac{\partial \Omega}{\partial m} = 0, \quad \frac{\partial \Omega}{\partial \Delta} = 0.
\]  

(34)

With the explicit form of the thermodynamic potential

\[
\Omega = \frac{(m-m_0)^2 + \Delta^2}{4G} - 8 \int \frac{d^3p}{(2\pi)^3} \left[ \zeta(E_\Delta^+) + \zeta(E_\Delta^-) \right],
\]  

(35)

where \( \zeta \) is defined as \( \zeta(x) = x/2 + \beta^{-1} \ln(1 + e^{-\beta x}) \), we
obtain the gap equations at zero temperature

\[
\begin{align*}
m - m_0 &= 8Gm \int \frac{d^3p}{(2\pi)^3} \left( \frac{1}{E_\Delta^+} + \frac{1}{E_\Delta^-} \right), \\
\Delta &= 8G \Delta \int \frac{d^3p}{(2\pi)^3} \left( \frac{1}{E_\Delta^+} + \frac{1}{E_\Delta^-} \right).
\end{align*}
\]  

(36)

Numerical solution of the gap equations is shown in Fig.5
Our results for the chiral and diquark condensates agree
quite well with the lattice data. For \( \mu_B < m_\pi \) the
ground state is the same as the vacuum state and the
baryon density keeps zero. For \( \mu_B > m_\pi \) the diquark
condensate and baryon density become nonzero. The critical baryon chemical potential $\mu_B^c$ is exactly the diquark mass $m_d$ in the vacuum, and the phase transition is of second order. Since the chiral symmetry is spontaneously broken at small $\mu_B$ and almost restored at large $\mu_B$, the effective quark mass $m$ plays an important role at small $\mu_B$ but can be neglected at large $\mu_B$. In fact, in the region above but close to the critical value $\mu_B^c$, the chiral condensate, effective quark mass and the diquark condensate as functions of $\mu_B$ can be well described by\cite{30}

$$\frac{m(\mu_B)}{m(0)} \approx \left(\frac{\langle \sigma \rangle(\mu_B)}{\langle \sigma \rangle(0)}\right)^2 = \left(\frac{m_\pi}{\mu_B}\right)^2,$$

$$\Delta(\mu_B) = \sqrt{1 - \left(\frac{m_\pi}{\mu_B}\right)^2},$$

(37)

which are consistent with the results from the chiral effective theory\cite{14}.

FIG. 6: The diquark condensate and the effective quark mass scaled by the quark mass in the vacuum as functions of $\mu_B/m_\pi$ at zero temperature.

To explain the BEC-BCS crossover, we further consider the dispersions of quark excitations,

$$E_{\Delta}^- = \sqrt{\left(\sqrt{p^2 + m^2} \mp \mu_B/2\right)^2 + \Delta^2}. \quad (38)$$

In the case of $\mu_B > 0$, $E_{\Delta}^-$ is the anti-particle excitation. In Fig. 7 we show the dispersion $E_{\Delta}^-$ at $\mu_B = 0.15, 0.5, 0.9$ GeV. Obviously, the fermion excitations are always gapped. At small $\mu_B$ with $\mu_B/2 < m(\mu_B)$, the minimum of the dispersion is at $|p| = 0$ where the energy gap is $\sqrt{\mu_N^2 + \Delta^2}$ with the corresponding non-relativistic chemical potential $\mu_N = \mu_B/2 - m$ introduced in the last subsection. However, at large $\mu_B$ with $\mu_B/2 > m(\mu_B)$, the minimum of the dispersion is shifted to $|p| \simeq \mu_B/2$ where the energy gap is $\Delta$. Such a phenomenon is a signal of the BEC-BCS crossover.

The BEC-BCS crossover is also reflected in the momentum dependence of the quark occupation number. In Fig. 7 we show also the quark momentum distribution $n_q(p)$ at $\mu_B = 0.15, 0.5, 0.9$ GeV. At small $\mu_B$ such as $\mu_B = 0.15$ GeV the occupation number is very small and smooth in the whole momentum region, while at large $\mu_B$ the occupation number becomes large near $|p| = 0$ and drops down with increasing momentum rapidly. When $\mu_B$ becomes very large, the occupation number is indeed of the BCS type.

![Figure 7: The quark energy dispersion and momentum distribution at several baryon chemical potentials at zero temperature.](image)

The numerical results of the chemical potential $\mu_N$ is shown in Fig. 8. The turning point from negative $\mu_N$ to positive $\mu_N$ is at about $\mu_B^0 \approx 230$ MeV, which is nearly the same as we obtained at the critical temperature shown in the last subsection. In fact, we can get an analytical expression for $\mu_B^0$ using equation (37). The BEC region is obtained by requiring $\mu_N < 0$, namely

$$\frac{\mu_B}{2} < m(\mu_B) \equiv m(0) \left(\frac{m_\pi}{\mu_B}\right)^2,$$

(39)

from which we obtain

$$\mu_B^0 = \left[2m(0)m_\pi^2\right]^{1/3},$$

(40)

it depends on the pion mass and effective quark mass in the vacuum. With the above chosen parameter set, we have $\mu_B^0 = 230$ MeV. When the effective quark mass in the vacuum varies from 300 MeV to 500 MeV, $\mu_B^0$ changes from 230 MeV to 270 MeV. Note that the explicit chiral symmetry breaking induced by nonzero current quark mass $m_0$ plays an important role in the study of BEC-BCS crossover. In the chiral limit with $m_0 = 0$, pions are massless and there will be no BEC state.
The second order effective action which is quadratic in the meson and diquark fields can be expressed as

$$S^{(2)}_{\text{eff}}[\sigma, \pi, \phi] = \int_0^\beta d\tau \int d^3x \frac{\sigma^2 + \pi^2 + |\phi|^2}{4G} + \frac{1}{4} \text{Tr} \{ \Sigma[\sigma, \pi, \phi] \Sigma[\sigma, \pi, \phi] \},$$

and can be evaluated as

$$S^{(2)}_{\text{eff}}[\sigma, \pi, \phi] = \frac{1}{2} \sum_k \left[ \frac{\delta_{ij}}{2G} - \Pi_{ij}(k) \right] \phi_i(-k)\phi_j(k)$$

in momentum space, where $\phi_i$ stand for the meson and diquark fields $\sigma, \pi, \phi$ and $\phi^*$, and the polarization functions $\Pi_{ij}$ are defined as

$$\Pi_{ij}(k) = i \int \frac{d^4p}{(2\pi)^4} \text{Tr} \{ \Gamma_i S_{\Delta}(p + k) \Gamma_j S_{\Delta}(p) \}$$

with $\Gamma_i$ being the interaction vertex defined in the Lagrangian density \( \mathcal{L} \).

Due to the off-diagonal elements of the quark propagator \( \Sigma \), those eigen modes of the system above $T_c$ are, in general case, no longer the eigen modes of the Hamiltonian in the superfluid phase. The new eigen modes are linear combinations of the old eigen modes and their masses are controlled by the determinant of the meson and diquark polarizations

$$\det \left[ \frac{\delta_{ij}}{2G} - \Pi_{ij}(k_0 = M, k = 0) \right] = 0.$$  \hspace{1cm} (44)

It can be analytically proven that while pions do not mix with the others and hence are still the eigen modes of the system, there is indeed a mixing among sigma, diquark and anti-diquark \( \Sigma \), and this mixing leads to a gapless Goldstone boson. We can show that $\Pi_{ud}$ and $\Pi_{dd}$ are proportional to $m_{\Delta}$ and $\Pi_{dd}$ is proportional to $\Delta^2$. Therefore, the mixing between sigma and diquark or anti-diquark is very strong in the BEC region where $m$ and $\Delta$ coexist and are both large, but the mixing can be neglected at large baryon chemical potential where $m$ approaches to zero.

C. Phase Diagram in $T - \mu_B$ Plane

We can now summarize the above results and propose a phase diagram of two color QCD in the $T - \mu_B$ plane. The phase diagram is shown in Fig.9. At low temperature and low baryon chemical potential, the matter should be in the normal hadron state. The thick dashed line at high temperature means the estimated phase transition from hadron gas to quark gas, which can not be calculated in the NJL model but should exist in the system. When the baryon chemical potential becomes larger than the pion mass in the vacuum, the diquark BEC appears and exists up to another critical baryon chemical potential $\mu_B^0$ indicated by the vertical dashed line. At high enough baryon chemical potential, the matter will become the BCS superfluid where the quark-quark Cooper pairs are condensed. Between the BEC and BCS states there should exist a crossover region, like the pseudogap regime in high temperature superconductor and ultracold fermion gas. Note that the transition from diquark BEC to BCS superfluid is a smooth crossover. Since two color QCD can be successfully simulated on lattice, such a BEC-BCS crossover can be confirmed by measuring the quark energy gap and comparing it with the diquark condensate. The pseudogap phase at high temperature can also be confirmed by investigating the quark spectral function.

III. DIQUARK BEC-BCS CROSSOVER IN THREE COLOR NJL MODEL

Let us now consider the realistic world with color degrees of freedom $N_c = 3$. The three color NJL model...
including the scalar diquark channel is defined as
\[
\mathcal{L} = \bar{\psi}(i\gamma^\mu \partial_\mu - m_0) \psi + G_s \left[ (\bar{\psi} \psi)^2 + (\bar{\psi} i\gamma_5 \tau \psi)^2 \right] + G_d \sum_{a=2,5,7} \left( \bar{\psi} i\gamma^\mu \tau_2 a \lambda \bar{\psi}^{(T)} \right) \left( \bar{\psi}^{(T)} C i\gamma^\mu \tau_2 \lambda a \psi \right),
\]
(45)
where \( \lambda_a \) are the Gell-Mann matrices in color space. Different from two color QCD, the scalar diquarks in three color case are color anti-triplets. Therefore, in real QCD, the problem of confinement becomes important. In this section, we will discuss the possible diquark BEC-BCS crossover without considering the effect of confinement.

### A. Scalar Diquark Mass in the Vacuum

We first discuss the scalar diquark mass in the vacuum with \( T = \mu_B = 0 \). In the random phase approximation, the diquark mass is determined by the pole equation
\[
1 - 2G_d \Pi_d(k_0 = m_d, \mathbf{k} = 0) = 0,
\]
(46)
where the diquark polarization function is defined as
\[
\Pi_d(k) = 4i \int \frac{d^4p}{(2\pi)^4} \text{Tr} \left[ i\gamma_5 \mathcal{S}(p + k)i\gamma_5 \mathcal{S}(p) \right]
\]
(47)
with the mean field quark propagator \( \mathcal{S}(p) = (\gamma^\mu p_\mu - m)^{-1} \). The effective quark mass \( m \) defined as \( m = m_0 - 2G_s \langle \bar{\psi} \psi \rangle \) satisfies the gap equation
\[
m - m_0 = 24G_s m \int \frac{d^4p}{(2\pi)^4} \frac{1}{\sqrt{\mathbf{p}^2 + m^2}}.
\]
(48)

Taking the trace in the Dirac space and summation over the quark frequency, the diquark mass \( m_d \) is controlled by
\[
1 = 8G_d \int \frac{d^3p}{(2\pi)^3} \left( \frac{1}{E_\mathbf{p} + m_d/2} + \frac{1}{E_\mathbf{p} - m_d/2} \right).
\]
(49)
If diquarks can exist as stable bound states in the vacuum, their mass must satisfy the constraint \( 0 < m_d < 2m \). As a consequence, the coupling constant in the scalar diquark channel should be in the region \( G_d^{\text{min}} < G_d < G_d^{\text{max}} \), where the upper limit is nearly model-independent,
\[
G_d^{\text{max}} = \frac{3}{2} G_s \frac{m}{m_0 - m} \approx \frac{3}{2} G_s,
\]
(50)
but the lower limit depends on the model parameters,
\[
G_d^{\text{min}} = \frac{\pi^2}{4 \left( \Lambda \sqrt{\Lambda^2 + m^2} + m^2 \ln \frac{\Lambda + \sqrt{\Lambda^2 + m^2}}{m} \right)}.
\]
(51)
In the three color NJL model, the model parameters are set to be \( m_0 = 5 \text{ MeV}, G_s = 4.93 \text{ GeV}^{-2} \) and \( \Lambda = 653 \text{ MeV}. For convenience, we take the coupling ratio \( \eta = G_d/G_s \) instead of \( G_d \). With the above parameter values, we find \( \eta_{\text{max}} \approx 1.55 \) and \( \eta_{\text{min}} \approx 0.82 \). For other possible parameter values, the lower limit is roughly in the region \( 0.7 < \eta_{\text{min}} < 0.8 \). Physically speaking, if \( \eta > \eta_{\text{max}}, the vacuum becomes unstable, and if \( \eta < \eta_{\text{min}}, a scalar diquark can decay into two quarks and becomes an unstable resonance.

The \( \eta \) dependence of the scalar diquark mass is shown in Fig.10. As estimated in \cite{3}, a scalar diquark is in a deeply bound state when the binding energy is in the region \( 200 \text{ MeV} < 2m - m_d < 300 \text{ MeV}, which corresponds to the diquark mass \( 300 \text{ MeV} < m_d < 400 \text{ MeV} \) and to the coupling ratio \( 1.3 < \eta < 1.4 \).

### B. Diquark BEC-BCS crossover

At large enough baryon chemical potential, the diquarks will condense. The diquark condensate is defined as
\[
\Delta_\mathbf{a} = -2G_d (\bar{\psi}^{(T)} C i\gamma^5 \tau_2 a \psi).
\]
(52)
Due to the color SU(3) symmetry, we can choose a specific gauge \( \Delta_2 = \Delta \neq 0, \Delta_5 = \Delta = 0 \). In this gauge, the red and green quarks participate in the condensation, but the blue one does not. We firstly consider the simplest case where the chemical potentials for the red, green and blue quarks are equal, \( \mu_r = \mu_g = \mu_b = \mu_B/3 \). General cases with color neutrality and vector meson coupling will be discussed in the following subsections. The thermodynamic potential at mean field level reads
\[
\Omega = \frac{(m - m_0)^2}{4G_s} + \frac{\Delta^2}{4G_d} - 4 \int \frac{d^3p}{(2\pi)^3} \left[ 2 \left( \zeta(E_\Delta^+ + \zeta(E_\Delta^-)) + \zeta(E_b^+ + \zeta(E_b^-)) \right) \right],
\]
(53)
where the quark energies are defined as
\[
E_\Delta^\pm = \sqrt{(E_\mathbf{p} \pm \mu_B/3)^2 + \Delta^2}, \quad E_b^\pm = E_\mathbf{p} \pm \mu_B/3.
\]
(54)
Minimizing the thermodynamic potential, we obtain the gap equations for the chiral and color condensates $m$ and $\Delta$ at zero temperature,

$$m - \mu_0 = 8G_d m \int \frac{d^3p}{(2\pi)^3} \frac{1}{E_p + \mu_B^\alpha} \left[ \frac{E_{p+}}{E_{\Delta}^+} + \Theta(E_b^-) \right] ,$$

$$\Delta = 8G_d \Delta \int \frac{d^3p}{(2\pi)^3} \left( \frac{1}{E_{\Delta}^-} + \frac{1}{E_{\Delta}^+} \right).$$

The above gap equations are almost the same as in the two color case, except the term $\Theta(E_b^-)$ in the first equation. For $\eta < \eta_{\text{min}}$, diquark condensation takes place at about $\mu_B^\alpha \approx 3m$ and the phase transition is of first order. In this case, there exists no BEC region where $\mu_N \equiv \mu_B - m = \mu_B/3 - m$ is negative. On the other hand, for $\eta_{\text{min}} < \eta < \eta_{\text{max}}$, the diquarks become condensed at $\mu_B^\alpha = 3m_d/2$ and the phase transition is of second order. The proof is as follows. For $\mu_B < 3m_d/2 < 3m$, the gap equation for $m$ keeps the same form as in the vacuum, and the gap equation for $\Delta$ becomes

$$1 = 8G_d \int \frac{d^3p}{(2\pi)^3} \left( \frac{1}{E_p + \mu_B^\alpha/3} + \frac{1}{E_p - \mu_B^\alpha/3} \right)$$

at the phase transition of color superconductivity with $\Delta = 0$. From the comparison with the diquark mass equation in the vacuum, the critical baryon chemical potential for color superconductivity should be $\mu_B^\alpha = 3m_d/2$. In this case, there must exist a BEC region where $\mu_N$ is negative, since at the phase transition point we have $\mu_N = \mu_B^\alpha/3 - m = m_d/2 - m < 0$.

In Fig. 11 we show the effective quark mass and diquark condensate as functions of baryon chemical potential. From the behavior of $\mu_N$, there exists indeed a diquark BEC region at intermediate baryon chemical potential. At sufficiently large baryon chemical potential the diquark condensate is in the BCS form.

In the diquark BEC region, we assume that the effective quark mass behaves as

$$\frac{m(\mu_B)}{m(0)} \approx \left( \frac{\mu_B^\alpha}{\mu_B} \right)^\alpha, \quad \alpha > 0.$$  

From our numerical calculation, the value of $\alpha$ depends on the coupling $\eta$. Taking $m(\mu_B) = \mu_B/3$ from $\mu_N = 0$ at the end point of the BEC, the diquark BEC region ends at

$$\mu_B^\alpha = \frac{3}{2} \left[ 2m(0)m_d^\alpha \right]^{\frac{1}{\alpha + 1}}.$$  

Therefore, the interval of $\mu_B$ for diquark BEC is

$$\Delta \mu_B = \mu_B^\alpha - \mu_B^- = \frac{3}{2} m_d \left[ \left( \frac{2m(0)}{m_d} \right)^{\frac{1}{\alpha + 1}} - 1 \right].$$

The largest BEC region takes place at $m_d \approx 185$ MeV corresponding to $\eta \approx 1.46$.

The critical temperature $T_c$ can be determined by solving the gap equations with $\Delta = 0$. Above the critical temperature, all scalar diquarks become degenerate and their polarization function reads $\Pi_d(k) = \Pi_3(k; 2\mu_B/3)$ with $\Pi_3$ listed in Appendix A. Similar to the calculation in the two color case, the diquarks are in bound state in the BEC region with $\mu_B/3 < m$, and become unstable resonances in the BCS region. The numerical results and discussions are quite similar to that in the two color NJL model.

C. Effect of Color Neutrality

In three color QCD, diquarks are no longer colorless and the requirement of color neutrality is not automatically satisfied once diquarks are included. This can be seen if we compute the expectation values of the color charges $\langle Q_a \rangle = \langle \bar{\psi} \gamma_a \gamma_0 \psi \rangle$. In the gauge with $\Delta_2 \neq 0$
and $\Delta S = \Delta T = 0$, we find $\langle Q_S \rangle \neq 0$. To solve this problem, we can introduce a color chemical potential $\mu_c$ corresponding to the 8-th color charge. It may be dynamically generated by a gluon condensate $\langle A_0^q \rangle$. The color charge neutrality condition is guaranteed by $\mu_c = \mu_q = \mu_b = \mu_B/3$ by $\mu_r = \mu_s = \mu_B/3 + \mu_S/3$ and $\mu_b = \mu_B/3 - 2\mu_S/3$. The color charge neutrality condition is guaranteed by $n_8 = -\partial \Omega/\partial \mu_S = 0$, namely

$$ \int \frac{d^3p}{(2\pi)^3} \left[ \frac{E_p^+}{E_\Delta^+} - \frac{E_p^-}{E_\Delta^-} - 2\Theta(-E_b^-) \right] = 0. \quad (60) $$

Taking into account the color neutrality, the recalculated effective quark mass and diquark condensate are shown in Fig.12. Comparing the behavior of the effective chemical potential $\mu_N \equiv \mu_r - m$ in the two cases with and without considering color neutrality, we find that the requirement of color neutrality disfavors diquark BEC. However, it does not cancel the BEC region completely.

**D. Effect of Vector Meson Coupling**

Now we ask the question whether there exists some mechanism that favors the diquark BEC. As we have seen, the diquark BEC happens in the beginning part of color superconductivity where the broken chiral symmetry starts to restore and the effective quark mass is still large enough. As proposed in [65], the quark interaction in vector meson channel may be a candidate to slow down the chiral symmetry restoration and enhance the BEC formation. Now we include a new interaction term to the NJL lagrangian,

$$ \mathcal{L}_v = -G_v \left[ (\bar{\psi} \gamma_\mu \psi)^2 + (\bar{\psi} \gamma_\mu \gamma_5 \tau \psi)^2 \right], \quad (61) $$

which corresponds to vector mesons. At finite density, a new condensate $\rho_v = 2G_v(\bar{\psi} \gamma_\mu \psi)$ which is proportional to the baryon number density should be considered. This condensate induces a new energy term $-\rho_v^2/4G_v$ in the thermodynamic potential and it enters the gap equations by replacing $\mu_B/3$ by $\mu_B/3 - \rho_v$. The gap equation for $\rho_v$ at zero temperature reads

$$ \rho_v = 8G_v \int \frac{d^3p}{(2\pi)^3} \left[ \frac{E_p^+}{E_\Delta^+} - \frac{E_p^-}{E_\Delta^-} + \Theta(-E_b^-) \right]. \quad (62) $$

In Fig.13 we calculate the effective quark mass and the diquark condensate at the coupling ratio $\eta = 1$ and for three values of the vector coupling $G_v$. For $G_v = 0$ the diquark BEC region is almost not visible, but for a reasonably large vector coupling such as $G_v/G_s = 0.3$ or 0.5, there appears a large diquark BEC region. It is clear that the vector meson channel really slows down the chiral symmetry restoration and favors the formation of diquark BEC. There may exist other mechanisms that favor BEC, such as the axial anomaly in QCD [66].

**E. Chromomagnetic Instability**

For realistic QCD matter in nature such as in compact stars, beta equilibrium and charge neutrality should be considered. These effects induce a chemical potential mismatch $\delta \mu$ between $u$ and $d$ quarks. Assuming the ground state to be a uniform phase, the mismatch effect will lead to an interesting gapless color superconductivity phase [67-68]. However, it was found that the gapless phase in the weak coupling region suffers the so-called chromomagnetic instability [69]. The Meissner masses squared of some gluons are negative. While the chromomagnetic instability indicates that the ground state of the superfluid may favor to be in some non-uniform phase such as LOFF phase [70, 71, 72], the instability may be cured in some region. Based on a two species model [73], it is found that the magnetic instabil-
ity should be fully cured in the BEC region. However, the 4-7th gluons’ instability is not yet examined. Here we try to complete this work.

The analytical expressions of the Meissner masses squared $m^2$ for the 4-7th gluons and $m^2$ for the 8th gluon are listed in Appendix B. We show the Meissner masses squared in Fig.14 in both BCS and BEC states. In the BCS case with $m \ll \mu_c$, our result is consistent with the analytical expression[69]. When we approach to the BEC region, both the 4-7th and 8th gluons’ instabilities are partially cured. In the BEC region with $m \geq \mu_c$, they are fully cured. Our investigation here is consistent with the study based on a non-relativistic model[74]. Since the chromomagnetic instability is fully cured, the ground state in the BEC region should be a uniform phase. We should address that such a phenomenon is quite similar to what happens in non-relativistic systems[78, 79, 80].

![Fig. 13](image1)

**FIG. 13:** The diquark condensate $\Delta$, effective quark mass $m$ and the chemical potential $\mu$ as functions of baryon chemical potential for several values of the vector couplings $G_v$ and at a fixed diquark coupling ratio $\eta = 1$ at zero temperature.

![Fig. 14](image2)

**FIG. 14:** The Meissner masses squared, scaled by $m_g^2 = 4\alpha_s\mu_r^2/(3\pi)$ with $\alpha_s$ being the QCD gauge coupling constant, for the 4-7th gluons (upper panel) and 8th gluon (lower panel) as functions of $\Delta/\delta\mu$.

### IV. Pion BEC-BCS Crossover at Finite Isospin Density

Another BEC-BCS crossover in dense QCD happens at finite isospin density where pions become condensed[4]. At small isospin density, the QCD matter is a BEC of charged pions, but at ultra high isospin density, deconfinement happens and the matter turns to be a BCS superfluid with quark-antiquark cooper pairing[4]. Therefore, there should be a BEC to BCS crossover when the isospin chemical potential increases. From the similarity between pions in three color QCD and diquarks in two color QCD, the pion superfluidity discussed in this section is quite similar to the diquark superfluid in Section II. We start from the two flavor Nambu-Jona-Lasinio model with only scalar meson channel,

$$\mathcal{L} = \bar{\psi} (i\gamma^\mu \partial_\mu - m_0) \psi + G_s \left[ (\bar{\psi}\psi)^2 + (\bar{\psi}i\gamma_5\tau\psi)^2 \right].\quad (63)$$

The key quantity describing the system is the partition function

$$Z = \int [d\bar{\psi}] [d\psi] e^{\int_0^\beta d\tau \int d^3x \left[ \mathcal{L} + \frac{\mu_I}{2} \bar{\psi} \gamma_0 \tau \psi \right]},\quad (64)$$

where the isospin chemical potential $\mu_I$ corresponds to the third component $I_3$ of the isospin charge. Using the Hubbard-Stratonovich transformation we introduce the auxiliary meson fields $\sigma$ and $\pi$, and the partition function
can be written as
\[
Z = \int [d\bar{\psi}] [d\psi] [d\sigma] [d\pi] e^{i\bar{\psi}\psi} \int d^3x L_{\text{eff}} \tag{65}
\]
with the effective Lagrangian
\[
L_{\text{eff}} = \bar{\psi} \mathcal{K}[\sigma, \pi] \psi - \frac{\sigma^2 + \pi^2}{4G_s} \tag{66}
\]
where the kernel \( \mathcal{K} \) is defined as
\[
\mathcal{K}[\sigma, \pi] = i\gamma^\mu \partial_\mu - m_0 + \frac{\mu_I}{2} \gamma_0 \tau_3 - (s + i\gamma_5 \tau \cdot \pi). \tag{67}
\]
Integrating out the quark degrees of freedom, we obtain
\[
Z = \int [d\sigma] [d\pi] e^{-S_{\text{eff}}[\sigma, \pi]} \tag{68}
\]
with the meson effective action
\[
S_{\text{eff}}[\sigma, \pi] = \int_0^\beta d\tau \int d^3x \frac{\sigma^2 + \pi^2}{4G_s} - \text{Tr} \ln \mathcal{K}[\sigma, \pi]. \tag{69}
\]

A. Pion Fluctuation at \( T > T_c \)

As we expected, when the isospin chemical potential \( \mu_I \) becomes larger than the pion mass \( m_\pi \) in the vacuum, the charged pions will condense at low temperature. In this subsection we focus on the region above the critical temperature \( T_c \) where the pion condensate vanishes. After the field shift for \( \sigma \), the effective action at zeroth order in meson fields gives the mean field thermodynamic potential \( \Omega \),
\[
\Omega = \frac{1}{\beta V} S^{(0)}_{\text{eff}} = \frac{(m - m_0)^2}{4G_s} + \frac{1}{\beta V} \ln \text{det} S^{-1}, \tag{70}
\]
where \( S \) is the quark propagator at mean field level
\[
S = \left( \gamma^\mu \partial_\mu - m + \frac{\mu_I}{2} \gamma_0 \tau_3 \right)^{-1}. \tag{71}
\]
The quadratic term of the effective action reads
\[
S^{(2)}_{\text{eff}}[\sigma, \pi] = \int_0^\beta d\tau \int d^3x \frac{\sigma^2 + \pi^2}{4G_s} - \frac{1}{2} \text{Tr} \{ S \Sigma[\sigma, \pi] S \Sigma[\sigma, \pi] \}, \tag{72}
\]
where \( \Sigma \) is defined as \( \Sigma[\sigma, \pi] = \sigma + i\gamma_5 \tau \cdot \pi \). Going to momentum space, the effective action can be evaluated as
\[
S^{(2)}_{\text{eff}}[\sigma, \pi] = \frac{1}{2} \sum_k \left[ \frac{1}{2G_s} - \Pi_\sigma(k) \right] \sigma(-k)\sigma(k) + \frac{1}{2G_s} - \Pi_{\pi_0}(k), \tag{73}
\]
where \( \pi_\pm = (\pi_1 \pm i\pi_2)/\sqrt{2} \) are the positively and negatively charged pion fields, and the polarization functions for the mesons can be evaluated as
\[
\Pi_\sigma(k) = N_\sigma k_\sigma, \quad \Pi_{\pi_0}(k) = N_\pi k_\pi, \quad \Pi_{\pi_+}(k) = N_{\pi+} k_{\pi+}, \quad \Pi_{\pi_-}(k) = N_{\pi-} k_{\pi-} \tag{74}
\]
where \( N_i \) is the color degree of freedom.

Without loss of generality, we consider the case \( \mu_I > 0 \) where the \( \pi_+ \) mesons become condensed at low temperature. The transition temperature \( T_c \) is determined by the well-known Thouless criterion
\[
1 - 2G_s \Pi_+(k_0 = 0, k = 0) \bigg|_{T = T_c} = 0 \tag{75}
\]
and the gap equation for the effective quark mass \( m \) derived from the first order derivative of the thermodynamic potential with respect to \( m \),
\[
\frac{m - m_0}{8N_c G_s m} = \int \frac{d^3p}{(2\pi)^3} \left[ 1 - f \left( E_p^+ \right) - f \left( E_p^- \right) \right] \frac{E_p}{E_p^+} \bigg|_{T = T_c} \tag{76}
\]
with \( E_p^\pm = E_p \pm \mu_I/2 \). The critical temperature as a function of isospin chemical potential is exactly the same as in Fig.1 if we replace the baryon chemical potential \( \mu_B \) by the isospin chemical potential \( \mu_I \). The diquark condensed phase starts at \( \mu_I = m_\pi^c \) and the critical temperature can be well described by
\[
T_c = T_0 \sqrt{1 - \left( \frac{m_\pi}{\mu_I} \right)^2}, \tag{77}
\]
where \( T_0 \) is again the temperature of chiral symmetry restoration at \( \mu_I = 0 \).

The energy dispersions of the mesons are defined by the poles of their propagators,
\[
1 - 2G_s \Pi_i(k_0 = \omega(k), k = 0) = 0, \quad i = \sigma, \pi_0, \pi_+, \pi_. \tag{78}
\]
Since the sigma and neutral pion do not carry isospin charge, they do not obtain an isospin chemical potential and their masses are defined as \( m_\sigma = \omega_\sigma(0) \) and \( m_{\pi_0} = \omega_{\pi_0}(0) \). However, for masses of charged pions, we should subtract the corresponding isospin chemical potential from the dispersions, namely we take \( m_{\pi_\pm} = \omega_{\pi_\pm}(0) + \mu_I \) and \( m_{\pi_-} = \omega_{\pi_-}(0) - \mu_I \). For \( \mu_I > 0 \), at the transition temperature \( T_c \), the \( \pi_+ \) mass is equal to the isospin chemical potential,
\[
m_{\pi_+}(T_c) = \mu_I. \tag{79}
\]
The numerical results for meson masses and dissociation temperatures are the same as in Figs.2 and 3 if we take the correspondence \( d \leftrightarrow \pi_+, \bar{d} \leftrightarrow \pi_-, \pi \leftrightarrow \pi_0 \) and \( \sigma \leftrightarrow \sigma \) between the two cases.

Similarly, we can investigate the spectral function \( \rho(\omega, k) \) for \( \pi_+ \),
\[
\rho(\omega, k) = -2\text{Im}D_R(\omega, k), \tag{80}
\]
where $D_R(\omega, k) = D(\omega + i\eta, k)$ is the analytical continuation of the pion Green function $D(i\omega_n, k)$ defined as

$$D(i\omega_n, k) = \frac{2G_s}{1 - 2G_s\Pi_{\pi}(i\omega_n, k)}. \quad (81)$$

The spectral function is also similar to that of diquarks in Section II. For $\mu_I < 2m, \pi_+ \to \pi_-$ decay into a quark-antiquark pair only when its energy satisfies $\omega > 2m - \mu_I$, otherwise it remains a stable bound state. However, for $\mu_I > 2m$, it can decay into a quark-antiquark pair at any energy and hence becomes an unstable resonance. The numerical result for the spectral function is similar to that shown in Fig II. In conclusion, with increasing isospin chemical potential, the pions above the critical temperature become more and more unstable and finally disappear, which indicates a BEC-BCS crossover.

We can also define an effective non-relativistic chemical potential $\mu_N = \mu_I/2 - m$. In the deep BCS limit with $\mu_I \to \infty$, we have $m \to 0$ and $\mu_N \to \mu_I/2$. In the deep BEC limit with $\mu_I \to m_\pi$, $m$ tends to be its vacuum value, and $\mu_N$ becomes negative and its absolute value approaches to half of the pion binding energy $2m - m_\pi$. The effective quark mass $m$ and the chemical potential $\mu_N$ at the critical temperature are the same as in Fig II, and the isospin chemical potential $\mu_I^0$ for the crossover is still about 240 MeV.

**B. Pion Condensation at $T < T_c$**

At low enough temperature, the pions become condensed, we should introduce not only the chiral condensate $\langle \sigma \rangle$ but also the pion condensates,

$$\langle \pi_+ \rangle = \frac{\Delta_\pi}{\sqrt{2}} e^{i\theta}, \quad \langle \pi_- \rangle = \frac{\Delta_\pi}{\sqrt{2}} e^{-i\theta}. \quad (82)$$

A nonzero pion condensate $\Delta_\pi \neq 0$ means spontaneous breaking of $U_3(1)$ symmetry corresponding to the isospin charge generator $I_3$. The phase factor $\theta$ indicates the direction of the $U_3(1)$ symmetry breaking. For a homogeneous superfluid, we can choose $\theta = 0$ without lose of generality. A gapless Goldstone boson will appear, which can be identified as the quantum fluctuation in the phase direction.

After a field shift $\sigma \to \langle \sigma \rangle + \sigma$ and $\pi_1 \to \Delta_\pi + \pi_1$, the effective action at zeroth order in meson fields gives the mean field thermodynamic potential,

$$\Omega = \frac{1}{\beta V} S_{\text{eff}}^{(0)} = \frac{(m - m_0)^2 + \Delta_\pi^2}{4G_s} + \frac{1}{\beta V} \ln \det S_\pi^{-1}, \quad (83)$$

where $S_\pi$ is the quark propagator in the pion superfluid at mean field level and can be evaluated as a matrix in flavor space,

$$S_\pi(p) = \begin{pmatrix} S_{uu}(p) & S_{ud}(p) \\ S_{du}(p) & S_{dd}(p) \end{pmatrix} \quad (84)$$

with the elements

$$S_{uu} = \frac{(i\nu_n + E_p^-)\Delta_\pi^-\gamma_0}{(i\nu_n)^2 - (E_p^-)^2} + \frac{(i\nu_n - E_p^+)\Delta_\pi^+\gamma_0}{(i\nu_n)^2 - (E_p^+)^2},$$

$$S_{dd} = \frac{(i\nu_n - E_p^-)\Delta_\pi^-\gamma_0}{(i\nu_n)^2 - (E_p^-)^2} + \frac{(i\nu_n + E_p^+)\Delta_\pi^+\gamma_0}{(i\nu_n)^2 - (E_p^+)^2},$$

$$S_{ud} = -i\Delta_\pi^+\gamma_5, \quad S_{du} = -i\Delta_\pi^-\gamma_5.$$

where $E_p^\pm = \sqrt{(E_p^-)^2 + \Delta_\pi^2}$ are quark energies.

The momentum distributions of quarks and antiquarks can be calculated from the positive and negative energy components of the diagonal propagators $S_{uu}$ and $S_{dd},$

$$n_u(p) = n_d(p) = \frac{1}{2} \left( 1 - \frac{E_p^-}{E_p^+} \right),$$

$$n_d(p) = n_u(p) = \frac{1}{2} \left( 1 - \frac{E_p^+}{E_p^-} \right). \quad (86)$$

The gap equations to determine the effective quark mass $m$ and pion condensate $\Delta_\pi$ can be obtained by minimizing the thermodynamic potential,

$$\frac{\partial \Omega}{\partial m} = 0, \quad \frac{\partial \Omega}{\partial \Delta_\pi} = 0. \quad (87)$$

With the explicit form of the thermodynamic potential

$$\Omega = \frac{(m - m_0)^2 + \Delta_\pi^2}{4G_s} - 4N_c \int \frac{d^3p}{(2\pi)^3} \left[ \zeta(E_p^+) + \zeta(E_p^-) \right],$$

we obtain the explicit gap equations at zero temperature,

$$m - m_0 = 4N_cG_sm \int \frac{d^3p}{(2\pi)^3} \frac{1}{E_p^- + E_p^+} \left( \frac{E_p^-}{E_p^-} + \frac{E_p^+}{E_p^+} \right),$$

$$\Delta_\pi = 4N_cG_s\Delta \int \frac{d^3p}{(2\pi)^3} \left( \frac{1}{E_p^-} + \frac{1}{E_p^+} \right). \quad (89)$$

The numerical results for $m$ and $\Delta_\pi$ are the same as in Fig II if we replace $\mu_B$ by $\mu_I$. The results agree well with lattice data \[10, 11, 12\] at least at small isospin chemical potential. For $\mu_I < m_\pi$, the ground state is the same as the vacuum state and the isospin density keeps zero, while for $\mu_I > m_\pi$, the pion condensate and isospin density become nonzero. In the isospin chemical potential region above but close to the critical value $\mu_I = m_\pi$, the effective quark mass and pion condensate can be well described by

$$\frac{m(\mu_I)}{m(0)} \approx \frac{\langle \sigma \rangle(\mu_I)}{\langle \sigma \rangle(0)} = \left( \frac{m_\pi}{\mu_I} \right)^4,$$

$$\frac{\Delta(\mu_I)}{\langle \sigma \rangle(0)} = \sqrt{1 - \left( \frac{m_\pi}{\mu_I} \right)^4}. \quad (90)$$
The explanation of the BEC-BCS crossover at zero temperature is similar to the diquark case in Section II. For $0 < \mu_I/2 < m(\mu_I)$, the minimum of the dispersion $E_{\pi}$ is at $|p| = 0$ where the energy gap is $\sqrt{\mu_N^2 + \Delta_{\pi}^2}$. For large enough $\mu_I$, the minimum of the dispersion is shifted to $|p| \approx \mu_I/2$ where the energy gap is $\Delta$. The momentum distribution for $u$ and anti-$d$ quarks is the same as in Fig. 7, which shows a BEC-BCS crossover at finite isospin chemical potential. Similar to the diquark case, the chemical potential $\mu_I^l$ for the crossover is

$$\mu_I^l = \left[2m(0)m_\pi^2\right]^{1/3},$$

which is about $230 - 270$ MeV when the parameter values change reasonably.

The second order effective action which is quadratic in the meson fields and controls the meson behavior can be evaluated as

$$S_{\text{eff}}^{(2)}[\sigma, \pi] = \int_0^\beta d\tau \int d^3x \frac{\sigma^2 + \pi^2}{4G_s} + \frac{1}{2} \text{Tr} \left\{ S_\pi \sum_{\sigma, \pi} S_\pi \Sigma[\sigma, \pi] \right\}. \quad (92)$$

In momentum space, it is related to the meson polarizations,

$$S_{\text{eff}}^{(2)}[\sigma, \pi] = \frac{1}{2} \sum_k \left[ \frac{\delta_{ij}}{2G_s} - \Pi_{ij}(k) \right] \phi_i(-k)\phi_j(k) \quad (93)$$

with $i, j = \sigma, \pi_+, \pi_-, \pi_0$, where the polarization functions $\Pi_{ij}$ are defined as

$$\Pi_{ij}(k) = iN_c \int \frac{d^4p}{(2\pi)^4} \text{Tr} \left[ \Gamma_a S_\pi(p + k) \Gamma_b S_\pi(p) \right]. \quad (94)$$

The masses of those new eigen modes in the superfluid phase are determined by the pole equation

$$\det \left[ \frac{\delta_{ij}}{2G_s} - \Pi_{ij}(k_0 = M, k = 0) \right] = 0. \quad (95)$$

It can be shown that the neutral pion does not mix with the other mesons and is still an eigen mode of the system, but sigma and charged pions are strongly mixed, and it is the mixing that results in a gapless Goldstone boson. From the proportional relations $\Pi_{\pi_+, \pi_-} \approx m\Delta_\pi$ and $\Pi_{\pi_+, \pi_-} \approx \Delta_\pi^2$ [30], the mixing between sigma and charged pions is very strong in the BEC region where $m$ and $\Delta_\pi$ are both large and coexist, but can be neglected at large isospin chemical potential.

In summary, the phase diagram of QCD at finite isospin density is shown in Fig. 15. At low temperature and low isospin chemical potential, the matter is in normal hadron gas with chiral symmetry breaking. With increasing temperature, there should be a phase transition from hadron gas to quark gas, indicated by the thick dashed line. When the isospin chemical potential becomes larger than the pion mass in the vacuum, the pion BEC appears and keeps until another critical isospin chemical potential $\mu_I^l$, which is indicated by the vertical dashed line. At high enough isospin chemical potential, the matter will enter the BCS superfluid where the quark-antiquark Cooper pairs are condensed. Between the BEC and BCS, there should exist a large crossover region. Since QCD at finite isospin chemical potential can be successfully simulated on lattice, such a BEC-BCS crossover can be confirmed by investigating the quark spectral function. When finite baryon density, charge neutrality and weak equilibrium are taken into account, they may have significant effect on the BEC-BCS crossover of pion condensation [72, 70, 77].

V. CONCLUSIONS

We have studied the BEC-BCS crossover in QCD at finite baryon or isospin density in the NJL model at quark level. We investigated the BEC-BCS crossover in two aspects: (1) Above the critical temperature of the superfluid, diquarks or mesons are stable bound states at low chemical potential but become unstable resonances at high chemical potential; (2) At zero temperature, the effective non-relativistic chemical potential, dispersions of fermion excitations and the fermion momentum distribution behavior significantly differently in the low and high chemical potential regions. The diquark BEC-BCS crossover in two color QCD at finite baryon density and the pion BEC-BCS crossover in real QCD at finite isospin density can be identified, since the quark confinement is not important in two color case. We expect that such a crossover can be confirmed in the lattice simulations, since the results from the NJL model agree quite well with the lattice data obtained so far. However, for real QCD at finite baryon density, whether there exists a diquark BEC-BCS crossover is still an open question, since the confinement in this case is quite important.

An interesting and important phenomenon we found in this paper is that the BEC-BCS crossover we discussed
is not induced by simply increasing the coupling constant of the attractive interaction but by changing the corresponding charge number. During the change of the number density, the chiral symmetry restoration plays an important role in the study of BEC-BCS crossover. When an chemical potential or fermion density mis-match between the two pairing species is turned on, the BEC-BCS crossover will be dramatically changed. The system may go from some non-uniform phases such as LOFF in the BCS region to some uniform gapless phase in the BEC region [78, 79, 80, 81, 82, 83, 84].

APPENDIX A: POLARIZATION FUNCTIONS $\Pi_1, \Pi_2, \Pi_3, \Pi_4$

The meson and diquark polarization functions $\Pi_1, \Pi_2, \Pi_3$ and $\Pi_4$ above the critical temperature for diquark or pion condensation can be evaluated as explicit functions of temperature $T$ and corresponding chemical potential $\mu$,

$$\Pi_1(k; \mu) = -\int \frac{d^3p}{(2\pi)^3} \left[ \frac{f_p^+ + f_q^+ - f_p^- - f_q^-}{k_0 - E_q + E_p} - \frac{f_p^+ + f_q^+ - f_p^- - f_q^-}{k_0 + E_q - E_p} \right] T_- $$

$$+ \left( \frac{2 - f_p^+ - f_q^+ - f_q^- - f_q^+}{k_0 - E_q + E_p} - \frac{2 - f_p^+ - f_q^+ - f_q^- - f_q^+}{k_0 + E_q - E_p} \right) T_+ $$

$$\Pi_2(k; \mu) = -\int \frac{d^3p}{(2\pi)^3} \left[ \frac{f_p^+ + f_q^+ - f_p^- - f_q^-}{k_0 - E_q + E_p} - \frac{f_p^+ + f_q^+ - f_p^- - f_q^-}{k_0 + E_q - E_p} \right] T_+ $$

$$+ \left( \frac{2 - f_p^+ - f_q^+ - f_q^- - f_q^+}{k_0 - E_q + E_p} - \frac{2 - f_p^+ - f_q^+ - f_q^- - f_q^+}{k_0 + E_q - E_p} \right) T_- $$

$$\Pi_3(k; \mu) = -2\int \frac{d^3p}{(2\pi)^3} \left[ \frac{f_p^+ - f_q^-}{k_0 + \mu - E_q + E_p} - \frac{f_q^- - f_p^+}{k_0 + \mu + E_q - E_p} \right] T_+ $$

$$+ \left( \frac{1 - f_p^+ - f_q^-}{k_0 + \mu - E_q + E_p} - \frac{1 - f_q^- - f_p^+}{k_0 + \mu + E_q - E_p} \right) T_- $$

$$\Pi_4(k; \mu) = -2\int \frac{d^3p}{(2\pi)^3} \left[ \frac{f_p^+ - f_q^-}{k_0 - \mu - E_q + E_p} - \frac{f_q^- - f_p^+}{k_0 - \mu + E_q - E_p} \right] T_+ $$

$$+ \left( \frac{1 - f_p^+ - f_q^-}{k_0 - \mu - E_q + E_p} - \frac{1 - f_q^- - f_p^+}{k_0 - \mu + E_q - E_p} \right) T_- $$

(A1)

where we have defined $\mathbf{q} = \mathbf{p} + \mathbf{k}$, $E_p = \sqrt{\mathbf{p}^2 + m^2}$, $f_\pm = f(E_p \pm \mu /2)$ with $f(x) = (1 + e^{x/T})^{-1}$ being the Fermi-Dirac distribution function and $T_\pm = 1 \pm (\mathbf{p} \cdot \mathbf{q} \mp m^2) / (E_p E_q)$.

APPENDIX B: MEISSNER MASSES SQUARED OF GLUONS

In this Appendix we list the explicit form of the Meissner masses squared $m_4^2$ for the 4-7th gluons and $m_8^2$ for the 8th gluon in two-flavor color superconductivity phase which are quoted from [83, 84].

$$m_8^2 = \frac{2g^2}{9} \int \frac{d^3p}{(2\pi)^3} \left[ 2 \left( 3 - \frac{\mathbf{p}^2}{E_p^2} \right) A(p) + \frac{\mathbf{p}^2}{E_p^2} B(p) \right],$$

$$m_4^2 = \frac{2g^2}{3} \int \frac{d^3p}{(2\pi)^3} \left[ 2 \left( 3 - \frac{\mathbf{p}^2}{E_p^2} \right) C(p) + \frac{\mathbf{p}^2}{E_p^2} D(p) \right]$$

(B1) (B2)
with the QCD gauge coupling constant $g$ and the functions

$$A(p) = \frac{(E_\Delta^2 - E_P^2) E_p^+ + \Delta^2 \Theta(-E_1) + \Theta(-E_2) - 1}{(E_\Delta^2 - (E_\Delta^2)^2) E_\Delta} - \frac{(E_\Delta^-)^2 - (E_\Delta^-)^2}{E_\Delta^-} E_P^- + \Delta^2 \Theta(-E_3) + \Theta(-E_4) - 1}{E_P^-} + 1,$$

$$B(p) = -\delta(E_1) - \delta(E_2) - \delta(E_3) - \delta(E_4),$$

$$C(p) = u_3^2 \left( \frac{(E_5 - E_3)}{E_5 + E_2} + \frac{(E_5 - E_1)}{E_5 + E_1} \right) + v_2^2 \left( \frac{(E_5 - E_2)}{E_5 + E_2} + \frac{(E_5 - E_3)}{E_5 + E_3} \right) + \frac{2}{E_p^2},$$

$$D(p) = u_3^2 \left( \frac{(E_5 - E_3)}{E_5 - E_2} - \frac{(E_5 - E_1)}{E_5 - E_1} \right) + v_2^2 \left( \frac{(E_5 - E_2)}{E_5 - E_2} - \frac{(E_5 - E_3)}{E_5 - E_3} \right),$$

where the quark energies are defined as

$$E_1 = E_\Delta^- - \delta \mu, \quad E_2 = E_\Delta^- + \delta \mu, \quad E_3 = E_\Delta^+ - \delta \mu, \quad E_4 = E_\Delta^+ + \delta \mu,$$

$$E_5 = E_\Delta^- - \delta \mu, \quad E_6 = E_\Delta^- + \delta \mu, \quad E_7 = E_\Delta^+ - \delta \mu, \quad E_8 = E_\Delta^+ + \delta \mu,$$

with the chemical potential difference $\delta \mu$ between $u$ and $d$ quarks and $E_\Delta^\pm$ and $E_b^\pm$ being listed in Section [III] the coherent coefficients $u_3^2$ and $v_2^2$ are defined as $u_3^2 = \left( 1 + E_\Delta^2 / E_\Delta^- \right) / 2$ and $v_2^2 = \left( 1 - E_\Delta^2 / E_\Delta^- \right) / 2$. Note that we have added the terms $1/E_P$ to $A$ and $2/E_P$ to $C$ to cancel the vacuum contribution [23]. In this way the Meissner masses squared are guaranteed to be zero in the normal phase with $\Delta = 0$.
