ABSTRACT

We present MUSE deep integral-field unit spectroscopy of three planetary nebulae (PNe) with high abundance discrepancy factors (ADF > 20): NGC 6778, M 1–42 and Hf 2–2. We have constructed flux maps for more than 40 emission lines, and use them to build extinction, electron temperature ($T_e$), electron density ($n_e$), and ionic abundances maps of a number of ionic species. The effects of the contribution of recombination to the auroral [N ii] and [O ii] lines on $T_e$ and the abundance maps of low-ionization species are evaluated using recombination diagnostics. As a result, low $T_e$ values and a downward gradient of $T_e$ are found toward the inner zones of each PN. Spatially, this nearly coincides with the increase of abundances of heavy elements measured using recombination lines in the inner regions of PNe, and strongly supports the presence of two distinct gas phases: a cold and metal-rich and a warm one with "normal" metal content. We have simultaneously constructed, for the first time, the ADF maps of O + and O 2+ and found that they centrally peak for all three PNe under study. We show that the main issue when trying to compute realistic abundances from either ORLs or CELs is to estimate the relative contribution of each gas component to the H i emission, and we present a method to evaluate it. It is also found that, for the studied high-ADF PNe, the amount of oxygen in the cold and warm regions is of the same order.

Key words: planetary nebulae: general – stars: mass-loss – stars: winds, outflows – binaries: close – ISM: abundances

1 INTRODUCTION

The abundance discrepancy problem is one of the major unresolved questions in nebular astrophysics, having being around for more than seventy years since Wyse (1942). In photoionised nebulae—both H ii regions and planetary nebulae (PNe)—optical recombination lines (ORLs) systematically yield larger chemical abundance values than collisionally excited lines (CELs). Solving this problem has obvious implications for the measurement of the chemical content of nearby and distant galaxies, because this is most often done using emission from their ionised interstellar medium from using CELs only. The discrepancy is generally parameterised in terms of the abundance discrepancy factor (ADF), which for a given ion is defined as the ratio between ionic chemical abundances derived from ORLs and CELs. The origin of this discrepancy has been the subject of strong debate in the past decades and several scenarios have been put forward (see e.g. García-Rojas et al. 2019; García-Rojas 2020, for details).

García-Rojas & Esteban (2007) proposed that the source of the abundance discrepancies may be different in H ii regions compared to PNe. In addition, detailed studies of H ii regions showed that high-velocity gas flows (Mesa-Delgado et al. 2009a,b) or the presence of high-density clumps, such as protoplanetary discs (proplyds, Tsamis et al. 2011; Mesa-Delgado et al. 2012), may have a significant impact upon the abundance determinations using CELs. Therefore, the hypothesis that several sources act to produce the observed discrepancies has gained strength.

⋆ E-mail: jogarcia@iac.es
In the case of PNe, several authors have proposed that the abundance discrepancy can be explained by the presence of two different components of gas (Liu et al. 2000, 2001; Tsamis & Péquignot 2005; Liu et al. 2006; Yuan et al. 2011, e.g.): a hot (∼10 000 K) gas with standard metallicity where the CELs can be efficiently excited, and a much cooler (∼1000 K) H-poor gas component with a highly enhanced content of heavy elements and almost no CEL emission, in which the bulk of heavy-element emission is produced.

Liu et al. (2006) speculated that the large ADF found in the PN Hf2–2 may be the result of the common envelope evolution of its known close binary central star. Indeed, Corradi et al. (2015), Jones et al. (2016) and Wesson et al. (2018) showed that the extremely large ADFs observed in some PNe are associated with the presence of close binary central stars.

Although the presence of two gas phases is not predicted by standard mass loss theories, several explanations have been propounded. Some of them are naturally linked to binarity, such as the hypothesis that the ORL-emitting gas is a low temperature, metal-enhanced phase likely produced by multiple episodes of mass loss and even fallback and reprocessing of the ejected material. This is supported by the significantly low mass of the ionised gas measured in PNe (Ali & Dopita 2017; Basurah et al. 2016; Yuan et al. 2018). However, this behaviour is not possible to favour any scenario owing to the lack of sufficient observational constraints.

To overcome this, several spectroscopic studies have been carried out, finding that in many PNe the ORL-emitting gas tends to concentrate at the central parts of the nebula. This is mainly found in PNe with close binary central stars and high ADFs (e.g. Corradi et al. 2015; García-Rojas et al. 2016; Jones et al. 2016; Wesson et al. 2018). However, this behaviour has also been seen in PNe with low-to-moderate ADFs and no indication of binarity (e.g. Garnett & Dinerstein 2001; Liu et al. 2001) and PNe with relatively high ADFs but no known close binary central star (e.g. M1–42; Climent 2016; García-Rojas et al. 2017).

In Section 4 the extinction maps and describe how uncertainties in the line fluxes are propagated. In Section 5 we present the methods followed to construct the ionization correction factors in the integrated spectra of PNe, or specific nebular components such as low ionization structures (Monteiro et al. 2013; Danehkar et al. 2013, 2014), or specific nebular components such as low ionization structures (Danehkar et al. 2016) or halos (Monteiro-Ibero et al. 2005). An extensive IFU survey of southern PNe using the 2.3m ANU telescope at Siding Spring Observatory (Ali et al. 2016; Basurah et al. 2016; Ali & Dopita 2017; Dopita et al. 2017, 2018; Ali & Dopita 2019) has provided valuable observational constraints on the physical structure of PNe. However, only a handful of these studies have addressed in some way the abundance discrepancy problem (Tsamis et al. 2008; Ali & Dopita 2019). Deeper studies of PNe can be performed using MUSE at the 8.2-m Very Large Telescope (VLT), as done by Walsh et al. (2016, 2018), and Monreal-Ibero & Walsh (2020). These authors used the nominal mode (MUSE-NOAO-N), which covers the wavelength range 480–930 nm, and hence does not include the recombination lines of the multiplet 1 of O II at λ = 465 nm.

The structure of the paper is as follows: in Section 2 we describe the observations and reduction processes. In Section 3 we present the methods followed to construct the emission line maps and describe how uncertainties in the line fluxes are propagated. In Section 4 the extinction maps are computed and discussed. In Section 5 we focus on the analysis of physical conditions using several line diagnostics. In Section 6 we give details on the ionic chemical abundance determinations and the ion abundance discrepancy factor. We also discuss the chemical analysis and determination of the ionization correction factors in the integrated spectra of each object. Finally, in Sections 7 and 8 results and conclusions are presented.

2 OBSERVATIONS AND DATA REDUCTION

Our targets were observed with the Multi Unit Spectroscopic Explorer (MUSE) integral-field spectrograph (Bacon et al. 2010) on the Very Large Telescope (VLT), in seeing-limited mode, on the night of 6 to 7 July 2016. The log of the observations is provided in Table 1. The sky conditions were rather good with a seeing of around 1 arcsec and under thin clouds. The instrument was used in its Wide Field Mode with the natural seeing (WFM-NOAO-E) configuration. This provides a nearly contiguous 1 arcmin2 field of view with 0.2-arcsec spatial sampling. In all cases, we used the extended mode of MUSE (WFM-NOAO-E), that covers the wavelength range 460–930 nm with an effective spectral resolution that increases from R = 1609 at the bluest wavelengths to R = 3506 at the reddest wavelengths. The data are available at the ESO Science Archive under Prog. ID 097.D-0241(A). For each object, observations were obtained with dithering and a rotation of 90° between each exposure to remove artefacts during data processing. Given that the objects are extended we obtained two sky frames on each sequence (see Table 1) to perform an adequate sky subtraction. A few short exposures were also taken to analyse the strongest emission lines. The data reduction was done with esoex, using the dedicated ESO pipeline (Weilbacher et al. 2016).
Figure 1. Composite RGB images of the MUSE field of view for NGC 6778 (top panel), M 1–42 (middle panel) and Hf 2–2 (bottom panel). [O\textsc{iii}] λ5007 emission is shown in blue, Hα in green and an average of [N\textsc{ii}] λ6583 and [S\textsc{ii}] λ6731 in red. The white squares represent the trimmed area of the data cubes that we study in this paper: 30 arcsec \(^2\) (150 \times 150 spaxels) for NGC 6778 and M 1–42 and 40 arcsec \(^2\) (200 \times 200 spaxels) for Hf 2–2. In all panels, north is up and east is to the left.

### Table 1. Log of the MUSE observations.

\( ^{a}\) Sky frames taken far enough away from the object to ensure that there is no nebular contamination.

For each individual frame the pipeline performs bias subtraction, flat-fielding and slice-tracing, wavelength calibration, geometric corrections, illumination correction using twilight sky flats, sky subtraction (telluric absorption/emission lines and continuum) making use of the sky frames obtained between science exposures. In the final steps of the reduction process, differential atmospheric correction and flux calibration were performed.

In the nominal wavelength range of MUSE, second-order contamination in the red is suppressed by a blue cut-off filter that also avoids ghosts in that region. This is not the case with the extended wavelength range that we use, which extends down to 465 nm, in order to have access to some important recombination lines. Thus, strong second-order contamination may appear redwards of 790 nm, that reaches levels of \(\approx 12\) per cent at wavelengths redder than 850 nm. For the reddest of our lines, we can assume that this contamination is not significant as there is little continuum in our nebulae and the chance that one emission line in the blue superimposes on one in the red at exactly twice its wavelength is minimal.

In this work we are mainly interested in the spatial distribution of the emission lines and the physical and chemical

2014, 2020). For each individual frame the pipeline performs bias subtraction, flat-fielding and slice-tracing, wavelength calibration, geometric corrections, illumination correction using twilight sky flats, sky subtraction (telluric absorption/emission lines and continuum) making use of the sky frames obtained between science exposures. In the final steps of the reduction process, differential atmospheric correction and flux calibration were performed.

In the nominal wavelength range of MUSE, second-order contamination in the red is suppressed by a blue cut-off filter that also avoids ghosts in that region. This is not the case with the extended wavelength range that we use, which extends down to 465 nm, in order to have access to some important recombination lines. Thus, strong second-order contamination may appear redwards of 790 nm, that reaches levels of \(\approx 12\) per cent at wavelengths redder than 850 nm. For the reddest of our lines, we can assume that this contamination is not significant as there is little continuum in our nebulae and the chance that one emission line in the blue superimposes on one in the red at exactly twice its wavelength is minimal.

In this work we are mainly interested in the spatial distribution of the emission lines and the physical and chemical
properties in the inner zones of PNe. Therefore, we trimmed the original data cubes to the central 30 arcsec (150 × 150 spaxels) for NGC 6778 and M 1–42 and the central 40 arcsec (200 × 200 spaxels) for Hf 2–2. In Fig. 1, we show RGB composite images of the three PNe along with a box indicating the extracted area for each data cube. The images clearly show that the trimmed sections fully cover the emission of M 1–42 and Hf 2–2. However, for NGC 6778 we focus on the bright central regions, neglecting the high-velocity northern and southern jets and part of the southern knot (see fig. 3 of Guerrero & Miranda 2012, for the nomenclature). These outer regions of NGC 6778 are not analysed in this work as the faint ORLs (critical to study the ADF) are not detected there.

We checked for possible saturation of the brightest lines in preliminary emission maps extracted using qfftsview ( Ott 2012). The [O III] λ5007 and λ4959 lines originate from the same energy level, so their intensity ratio only depends on the transition probabilities (A-values) ratio, being the most accepted theoretical value 2.98 ( Storey & Zeippen 2000). We computed the [O III] λ5007/λ4959 intensity ratio maps and concluded that in NGC 6778 and M 1–42 this ratio departs significantly from the theoretical value in most exposures. This indicates that the [O III] λ5007 line is saturated in a large number of spaxels in the field of view, and hence we decided to measure only the [O III] λ4959 line in these PNe. Similarly, we found for the same two objects that the [N II] λ6583 line is also saturated in a number of spaxels, as the observed [N II] λ6583/λ6548 line ratio departs significantly from the theoretical value of 2.94 (see Froese Fischer & Tachiev 2004), so we neglected this line in any calculations for NGC 6778 and M 1–42. Finally, Hα is also slightly saturated in some spaxels of M 1–42. In Section 4 we discuss the actions taken to address this issue. In Hf 2–2, we found no signs of line saturation.

3 EMISSION LINE MEASUREMENTS

To obtain the emission line maps with their uncertainties, we used a PYTHON code that combines tools from the Astropy (Astropy Collaboration et al. 2013, 2018) and PYNECKIT (an extensible spectroscopic analysis toolkit for astronomy; Ginsburg & Mirocha 2011) packages. The code reads in the MUSE data cubes and performs individual Gaussian fits to previously selected emission lines in each spaxel. The user supplies initial guesses for the line centre, amplitude and width and the fit is then performed in a specified region of the spectra extracted around the line centre. The fits are done using the Levenberg-Marquardt least-squares routine ( MPTIF; Markwardt 2009). We adopted the variance estimates of the data cube derived in the reduction process as the data uncertainties, which were treated as weights in the fits. The code outputs maps of the emission line flux, central wavelength, width and continuum as well as their respective uncertainties. We quadratically added an extra 5 per cent to the uncertainty in the line fluxes to account for systematic sources of error.

Continuum maps in the blue and red zones off the Paschen jump were also constructed using the automated line-fitting algorithm ALFA ( Wesson 2016), which provides continuum measurements at 8100 and 8400 Å.

3.1 Emission line maps

For each PN, we constructed flux maps of more than 40 emission lines. We masked out the spaxels with very low signal-to-noise ratio: only spaxels with $S/N > 0.05\times S/N_{\text{max}}$ in the unreddened $F(H\beta)$ map were considered. This criterion does not affect the main body of each nebula and only masks spaxels where the measured quantities are likely unreliable.

In Figs. S1, S2 and S3 of the supplementary material (online only) we present the unreddened flux maps of some of the most relevant emission lines in NGC 6778, M 1–42 and Hf 2–2, respectively. We show the emission maps by increasing element mass and increasing ionization stage. Maps are displayed on logarithmic scale to enhance the fainter emitting structures of each line. For each nebula, the ionization structure is apparent, with the higher ionization stages emitted more internally than the lower ionization ones. A remarkable exception to this behaviour is found for the CNO recombination lines, which reveal that the emission is produced in a volume more internal than that expected for the CEL emission of the corresponding ions (see Section 3.1.2). The three PNe exhibit moderate excitation with centrally peaked H β emission. However, only M 1–42 shows clear emission of the high-excitation [Ar v] line in its central parts, while NGC 6778 reveals a quite faint emission of this line, which is completely absent in Hf 2–2. The flux distribution of the main gas shells in each nebula can be inferred from the Hβ emission line maps on logarithmic scale presented in Fig. 2, for which we have adopted the mask defined above.

3.1.1 Morphology from the emission line maps

The morphology and kinematics of NGC 6778 have been extensively studied by Guerrero & Miranda (2012). These authors found that its main nebular shell consists of a disrupted equatorial ring and kinematically disturbed bipolar lobes. The highly distorted and fragmented equatorial ring, aligned close to the east-west direction, can be easily seen in the [O I], [N II], [S II] and [N II] emission line maps in Fig. S1 of the supplementary online data. On the other hand, the H I, He I and mid-ionization ions like [O III], [S III] and [Ar III] show a much smoother spatial distribution than the low-ionization ones.

M 1–42 was imaged by Schwarz et al. (1992) using narrow-band Hα and [O III] λ5007 filters. It exhibits an elliptical morphology, with a slightly more extended angular diameter in Hα than in [O III], and a ring-like structure with a faint lobe to the north. More recently, Guerrero et al. (2013) analysed deep Hα HST images and catalogued M 1–42 as an elliptical PN with ansae/bipolar lobes. The presence of such ansae is evident in Fig. 1, where it is clear that they are relatively bright in low-ionization emission lines. However, they are quite faint in Hβ and, therefore, have been excluded from our analysis following the criteria applied to build our maps (see above).

Hf 2–2 was also observed by Schwarz et al. (1992). This PN displays a highly symmetric morphology, with an inner disc-like shell very bright in [O III] and an outer limb-brightened shell with an angular diameter of $\approx 20$ arcsec. The inner disc (shell) is brighter in [O III] and has a central cavity, while the outer limb-brightened shell is bright in Hα and low-ionization species, such as [O I], [O II], [N II]
and [S II], where the emission of the shell is shown to be disrupted in several bright knots. This could be consistent with the PN being bipolar and observed nearly pole-on—such a nebular inclination would be consistent with the orbital inclination of the central binary star (Hillwig et al. 2016). Nevertheless, a detailed spatio-kinematical model is needed to confirm this hypothesis, but archival VLT–UVES high-resolution spatially-resolved spectroscopy (Fig. 3) obtained in long-slit mode (see Tyndall et al. 2012, for a full description of this setup and the data reduction) is consistent with a low inclination (i.e. pole-on) bipolar morphology similar to that of Sp1 (Jones et al. 2012).

### 3.1.2 Emission line maps of heavy element RLs

Only a handful of works have shown the spatial distribution of faint recombination lines in PNe, such as O i, O II and C II (see e.g. Tsamis et al. 2008; Ali & Dopita 2019). To our knowledge, this is the first time this has been done in high-ADF PNe using IFU data. As we point out in Section 1, the emission of these lines is more centrally concentrated than the CEL emission of the same ions in PNe with high ADFs. This is clearly illustrated in Fig. S1 of the supplementary material, where the RL emission of the O i triplet \( \lambda \lambda 7771+74+75 \) is produced in more central parts than the [O II] \( \lambda \lambda 3729+39 \) CEL emission. The same applies to the RL emission of O II \( \lambda \lambda 4649+50 \) RLs and the [O II] \( \lambda \lambda 4959+50 \) CEL. Moreover, the spatial distribution of the C II \( \lambda \lambda 4642 \) and N II \( \lambda \lambda 5579 \) RLs resembles that of the O II \( \lambda \lambda 4649+50 \) RLs, although the C \( ^+2 \), N \( ^+2 \) and O \( ^+2 \) ions do not share exactly the same ionization potential range (see Section 6.2 for a more detailed discussion on this).

### 3.2 Using Monte Carlo simulations to propagate uncertainties

We used a Monte Carlo (MC) based method to assess the uncertainties in the physical and chemical spatial properties of the objects derived from the pipeline. After obtaining the extracted emission line maps (see Section 3), we create 150 artificial “fake” maps for each emission line. Line intensities in each spaxel are generated using random values obtained from a normal distribution with a mean value equal to the observed intensity and a standard deviation given by its uncertainty. This produces data cubes of size 150 × 150 × 151 or 200 × 200 × 151, depending on the object, for each emission line (and continuum value). These synthetic data cubes are then used in each step of the pipeline to compute and apply the reddening corrections, to determine the physical parameters (electron temperatures and densities), to determine the ionic abundances corresponding to each emission line and the adopted ionic abundances and to determine the ionic ADFs. For each of these parameters and each spaxel of the object image, we then obtain a distribution of 151 values that allow to determine the “original” value obtained from the observed line intensity, the “median” value obtained from the distribution and the “standard deviation” of these values.

The line intensities obtained from the integrated spectra (see Section 6.5) follow the same process: we actually added the integrated value of each emission line to the pixel (0,0) of the corresponding map, ensuring that the integrated value follows exactly the same steps in the analysis pipeline than the individual spaxels of the maps.

### 4 extinction maps

The extinction coefficient, \( c(H \beta) \), maps were constructed using PYNEB (Luridiana et al. 2015) by comparing the observed and theoretical Hα/Hβ line ratios and adopting the
Galactic extinction law by Fitzpatrick (1999) and the theoretical H1 line ratios from Storey & Hummer (1995) for $T_e = 10,000 \text{ K}$ and $n_e = 1,000 \text{ cm}^{-3}$. Notice that we did not try to correct the H1 emission lines for the adjacent He11 faint emissions, because at the relatively moderate excitation of our three PNe this contribution was always below 1 per cent, i.e. within the uncertainties. In M1–42, we detected that Hα is slightly saturated in a small region located few arcseconds to the northwest of the central star, which provides an apparent lower extinction and also produces artifacts in the adjacent pixels. For this nebula we tried to construct the extinction map using a shorter exposure of 60s. However, the extracted extinction map had large uncertainties in the outer parts of the nebula, which propagated to the computed physical conditions and chemical abundances. Therefore, we decided to adopt a different strategy for the computation of the extinction map for M1–42: we built additional extinction maps using Paschen (P9 to P12) over Hβ line ratios and computed the median c(Hβ) map considering all the available maps. This strategy diluted the saturation effect in the inner parts of the nebula and conserved an adequate determination of the extinction coefficient in the outer parts. This is shown in Fig. 4, where we plot the ratio between the median c(Hβ) map and the one computed using only Hα/Hβ; the ratio is almost constant and close to 1 in all the nebula with the exception of the saturated spaxels.

The extinction maps for each PN are shown in Fig. 5. In Table 2 we show the median c(Hβ) obtained using different H1 line ratios for our three objects, as well as the median value and standard deviation in the integrated spectra. For NGC6778 and Hf2–2, only the c(Hβ) obtained from the Hα/Hβ ratio is considered. Overall, the c(Hβ) values obtained using different H1 lines are in a relatively good agreement for all the objects, with the exception of the value obtained with the P10/Hβ ratios, which is systematically lower and may be indicative of telluric absorption affecting the line measurements of the P10 line, especially in the case of Hf2–2, for which the signal-to-noise ratio of the lines is the lowest in our sample (and the exposure times the largest by far).

In general, the maps do not exhibit large extinction variations for each nebula, although relatively small differences can be appreciated. In the case of NGC6778, it is apparent that the higher extinction values follow a region delimited by the curved jets, where Hα dominates the emission of the nebula (see the Hα/O III) and [N II]/[O III] ratios in Guerrero & Miranda 2012). For M1–42, the extinction is quite constant, with the exception of the central cavity, where the extinction is consistently lower, and a thin slab of gas northwest of the central cavity with somewhat higher extinction. Finally, Hf2–2 apparently shows a slightly higher extinction in the inner parts surrounded by a ring that delimits a lower extinction.

5 MAPPING THE PHYSICAL CONDITIONS

The physical conditions were computed with PYNEB v1.1.15 (Luridiana et al. 2013) using the atomic data set presented in Table 3. As our targets have the peculiarity of being strong emitters of heavy-element recombination lines, we have to be careful when computing physical conditions for the different plasma components. Thus, in this section we describe the methodology followed to compute the physical conditions using classical CEL diagnostics, paying special attention to the potentially strong effect of the recombination contribution to the faint auroral lines. We finally describe how we compute $T_e$ using recombination line and continuum diagnostics.

5.1 Electron temperatures and densities from CELs

Every 2D data set of a given emission line considered in this work contains 150° or 200° pixels, depending on the object. For each pixel, we consider an MC distribution of 150 “fake” observations (see Section 3.2). This leads to between three and six million intensity values for each emission line. Computing the values of the electron temperature and density corresponding to the intersection of two diagnostic line ratios in the $T_e$–$n_e$ plane for each one of these data points may be very CPU time consuming. To speed up the computation process, we took advantage of the PYNEB Diagnostic.getCrossTemDen method that uses a Machine Learning (ML) algorithm (from v1.1.13 on). An artificial neural network (ANN) is trained with 900 pairs of diagnostic line ratios corresponding to the $T_e$–$n_e$ pairs covering the range of expected values ($3000 \leq T_e [\text{K}] \leq 30000$ and $1 \leq \log_{10}(n_e [\text{cm}^{-3}]) \leq 9$). This training phase is done only once and takes a few minutes. The ANN is then used to predict the $T_e$–$n_e$ values corresponding to the millions of observed and MC line ratios in less than two seconds. The
ANN is implemented directly in PYNEB using the MUSE facility (Morisset et al., in prep.) that, in the present case, interfaces the scikit-learn package (Pedregosa et al. 2011). The ANN consists of three hidden layers of 10, 20 and 10 cells using tanh activation. The solver used is lbfgs. The input line ratios have been transformed into their logarithmic values and scaled using the StandardScaler routine from sklearn. More details on the MUSE facility will be provided in Morisset et al. (in prep).

We obtain the electron densities and temperatures for both each observed and MC spaxel, for the pairs of diagnostic line ratios described in Table 4. We adopted a classical two-zone scheme, i.e. we use the $T_e$ determined from [N ii] $\lambda$5755/186548 and [S iii] $\lambda$6312/184969 for the low ($\leq$ 17 eV) and high ($> 17$ eV) ionization potential zones, respectively (see Section 6). It is important to emphasize that, although [S iii] $\lambda$4969 emission line can be affected by H2O and O2 telluric absorption bands, the MUSE pipeline effectively removes such signatures using dedicated sky exposures (see Section 2). The electron density is determined using [S iii] $\lambda$6716/16716 in both zones. Generally, [Cl iii] and/or [Ar iv] diagnostics are better suited for the high-ionization zone. However, the [Cl iii] density diagnostic leads to rather similar values to $n_e$([S iii]) in the main body of each PN, but a much higher $n_e$ in the external parts where the [Cl iii] lines emissivity significantly drops (see Figs. S1 to S3 of the supplementary material). Electron densities based on [Ar iv] are higher but the maps are quite noisy. This behaviour is due to the intrinsic difficulty in deblending He i $\lambda$4713 from [Ar iv] $\lambda$4711. Taking into account that in the density range below 10$^4$ cm$^{-3}$ (which is the case for all the PNe studied here), the effect of $n_e$ on the absolute values derived for $T_e$([S iii]) is small, we avoid the use of this $n_e$ diagnostic. In Figs. 6 (and S7 and S8 of the supplementary material) we show the obtained $T_e$ (upper panels) and $n_e$ (bottom panels) for NGC 6778, M1–42 and HF2–2, respectively. In these figures, we have corrected for the recombination contribution to the auroral [N ii] $\lambda$5755 line assuming $T_e$ = 4000 K for the zone where recombination emission arises (see next Sections). Physical conditions diagnostic maps assuming $T_e$ = 10000 K and no correction are available in the online material.

### Table 3. Atomic data sets used for the CELs and ORLs.

| Ion     | Transition Probabilities | Collision Strengths |
|---------|--------------------------|----------------------|

### Table 4. Diagnostic line ratio pairs used to compute the physical parameters. The $T_e$–$n_e$ diagnostics used to determine ionic abundances are shown in bold font.

| Ioniz. Zone | $T_e$ diagnostic | $n_e$ diagnostic |
|-------------|------------------|------------------|
| Low         | [N ii] $\lambda$5755/186548 | [S iii] $\lambda$6731/16716 |
| High        | [S iii] $\lambda$6312/184969 | [Cl iii] $\lambda$4553/45518 |

5.2 Correction for recombination contribution

Rubin (1986) pointed out that the low-lying metastable levels of several CELs, including the auroral [N ii] $\lambda$5755 line and trans-auroral [O i] $\lambda$4730+30 lines can be significantly populated by recombination processes. To illustrate how this can affect the emission maps, in Figs. S1 to S3 of the supplementary material one can compare the spatial distribution of [S iii] $\lambda$6731 and [O i] $\lambda$47329+30 (labelled as [O i] $\lambda$7330+30). Although O$^+$ and S$^+$ have similar ionization potential ranges, the spatial distribution of their emission are remarkably different in [O i] $\lambda$4730 and [S iii] $\lambda$6731 lines (see Figs. S1 to S3 of the supplementary material). As several authors have indicated (see Wesson et al. 2018, and references...
therein), second-row elements such as O and N can show a strong enhancement of their recombination lines. However, this does not seem the case for third-row elements (like S), so it is not expected that S lines can be affected by any recombination process.

Liu et al. (2000) proposed some recipes to compute the recombination contribution to [N ii] 5755 assuming $T_e = 4000$ K has been considered. The same maps for M 1–42 and Hf 2–2 can be found in Figs. 7 and S8 of the supplementary material.

Figure 6. Electron temperature, $T_e$, and density, $n_e$, maps obtained from the combination of different temperature and density diagnostics for NGC 6778. The recombination contribution to [N ii] 5755 assuming $T_e = 4000$ K has been considered. The same maps for M 1–42 and Hf 2–2 can be found in Figs. 7 and S8 of the supplementary material.

We have decided to apply a more direct method to estimate this contribution and, therefore, would need an iterative process to properly apply the correction. For these reasons, we have decided to apply a more direct method to estimate this contribution. We used the radiative recombination coefficients for the metastable levels of [N ii] and [O ii] calculated by Pequignot et al. (1991) and radiative recombination coefficients for N ii 45769 (Rang et al. 2011) and O ii 44649+50 (Storey et al. 2017), which are the brightest N ii and O ii ORs in our spectra, and used their extinction corrected emission maps to estimate the contribution by simply applying the following:

$$I(5755)_{\text{corr}} = I(5755) - \frac{j_{5755}(T_e, n_e)}{j_{5679}(T_e, n_e)} \times I(5679)$$

(1)

$$I(7320 + 30)_{\text{corr}} = I(7320 + 30) - \frac{j_{7320+30}(T_e, n_e)}{j_{4649+50}(T_e, n_e)} \times I(4649 + 50),$$

(2)

where $j_{\lambda}(T_e, n_e)$ are the recombination emissivities for each line. In these equations, $n_e$ was set to a constant value of 10$^3$ cm$^{-3}$ and $T_e$ was explored using three different values (4000, 4000 and 8000 K). In Fig. 7 we present the [N ii] 5755 maps assuming $T_e = 4000$ K for the recombination emission (right panels). It is evident that the effect is not negligible in any of the three PNe and can be dramatic in Hf 2–2, where almost all the observed emission of the auroral [N ii] line is due to recombination.

We have checked that the corrections obtained using our recipes are within 10 per cent of those derived from Liu et al. (2000). As we pointed out before, the advantage of our method is that it does not rely on the ionic abundances of the recombining ions, and then can be applied at an earlier step in the analysis pipeline, before starting to compute the ionic abundances.

Possible effects of continuum fluorescence on the intensities of the C ii, N ii, O i and O ii lines in the low-ionization PN IC 418 were explored by Escalante et al. (2012). These authors found that continuum fluorescence significantly affects the intensity of the N ii 45769 ORL (by $\approx 70$ per cent) and O ii 44649+50 ($\approx 20$–30 per cent), leaving the C ii 45542, 6462 and O i 4771+74+75 lines unaffected. Given that our objects are all highly excited PNe, we do not expect such a high contribution of fluorescence to be responsible for the excitation of N ii and O ii lines from the s, p and d states. However, as we will see in detail in Section 6.2, the excitation in the cold gas is much lower than in the “normal” gas in all our targets, so we cannot completely rule out that fluorescence can contribute to some extent to the observed
fluctuations. Unfortunately, without detailed information from the UV spectra of the ionizing sources, we cannot evaluate the significance of this effect on the observed intensities.

Last but not least, it is important to emphasize that in highly ionized nebulae the recombination contribution can also be important for the auroral [OIII] $\lambda 4363$ CEL (Liu et al. 2000). However, we are currently unable to check for this as [OIII] $\lambda 4363$ lies outside the wavelength range of our MUSE data. However, this effect should be carefully assessed when computing $T_e$ ([OIII]), because in some highly-excited PNe with high ADFs, the auroral [OIII] $\lambda 4363$ line could be strongly excited by recombination, making this $T_e$ diagnostic unreliable (see Gómez-Llanos et al. 2020).

5.2.1 Effect of the recombination contribution on the [NII] electron temperature maps.

As we have described above, the recombination contribution to the auroral [NII] $\lambda 5755$ line strongly affects the measured line flux in high-ADF PNe. In Fig. 8, we show the $T_e$([NII] $\lambda 5755$) maps with no recombination contribution correction (first column panels) and adopting recombination contribution corrections using different temperatures for the recombination emission (1000, 4000 and 8000 K; second, third and last column panels, respectively) and adopting $n_e$([SII]). For each object, we present all the maps with the same temperature scale to emphasize the $T_e$ differences between them. It is apparent from Fig. 8 that neglecting the recombination correction for the [NII] $\lambda 5755$ line translates in extremely high $T_e$ determinations, especially in the central zones of M1–42 and Hf2–2, where values over 20000 K are reached. Such large values are not obtained when the [SII] line ratio is used (see Fig. 6 for NGC 6778 and corresponding figures in the supplementary material for the other two PNe). We do not see any physical justification for the presence of low ionization gas (emitting [NII] lines) at high temperature, when the intermediate ionization gas trace by the [SIII] emission is almost at a uniform temperature. We then attribute this high temperature to the lack of correction for the recombination contribution to the [NII] $\lambda 5755$ line. Assuming a very low $T_e$ = 1000 K for the recombination zone (second column panels in Fig. 8) does not fix the problem: the $T_e$([NII] $\lambda 5755$) is still too high in the central zones of each nebula implying an abnormal behaviour in the component of the gas where the bulk of CEL emission arises. On the other hand, adopting a similar $T_e$ for the gas where recombination emission is produced has the opposite effect, and $T_e$ significantly drops in the inner parts. Finally, adopting a value of $T_e$ = 4000 K for the recombination emission zone provides a $T_e$([NII] $\lambda 5755$) map whose structure is quite similar to that of the $T_e$([SIII] $\lambda 6312$) map for NGC 6778 and M1–42 (see Fig. 6 and Fig. S7 of the supplementary material). For Hf2–2, the $T_e$([NII] and $T_e$([SIII]) maps still seem quite dissimilar. However, the uncertainties in the central parts of this PN are extremely high as the $T_e$([NII] $\lambda 5755$) line is completely dominated by recombination in the whole nebula, with the exception of its outermost zones (see Fig. 7), where, in fact, the obtained $T_e$([NII]) and $T_e$([SIII]) best agree. We therefore adopt $T_e$ = 4000 K as the characteristic $T_e$ to correct for the recombination contribution in the three PNe under study. It is important to note here that the value for the temperature adopted to compute the [NII] $\lambda 5755$ recombination contribution may not be fully related to the electron temperature in the cold region: the correction is obtained by combining emissivities determined using atomic data from Pequignot et al. (1991) and Fang et al. (2011) (see previous Section), that may suffer from high uncertainties. The exact temperature for the cold region may actually be much lower than the adopted value. Therefore, it should be considered as a tunable parameter for the recombination correction.

Adopting $T_e$ = 4000 K is a good compromise for our PNe. It is very similar to the $T_e$ values obtained in their central zones from $T_e$ recombination diagnostics (see next Section), which only provide qualitative information on $T_e$ in the low-temperature plasma, as they are based on H1 and He1 emission that is present in both components and strongly depends on the relative weight of the low-temperature region (see Section 7). The only way to break the introduced degeneracy is to have a $T_e$ diagnostic of the cold region, such as O1 $\lambda 4069/\lambda 4169$ (see Storey et al. 2017), which unfortunately is missing in the MUSE data owing to the lack of wavelength coverage below 4600 Å.

Although the effect of the recombination contribution to the auroral lines has been proven to be dramatic when mapping physical conditions, it is mandatory to check this effect when integrating the whole or a significant part of the volume of the nebula, as the effect could be diluted owing to the radically different weight of recombination emission in the central and external zones of the nebula. In Section 6.5 we will discuss how the recombination contribution affects the physical conditions and chemical abundance determinations in the integrated spectra.

5.3 Electron temperatures from He I recombination lines and Paschen continuum.

The electron temperature can also be determined from the $T_e$ sensitive He I $\lambda 4728/\lambda 6678$ recombination line ratio, following the procedure in Zhang et al. (2005). We have used the fitting coefficients computed by Méndez-Delgado et al. (2021) to account for weak density dependencies and then interpolated linearly (their table 7) the coefficients needed to solve their equation 4. For the densities considered in this work, the sensitivity of the He I $\lambda 4728/\lambda 6678$ line ratio to $T_e$ is rather low for $T_e$ lower than 20000 K.

For the determination of the electron temperature from the Paschen jump (PJ), we define the jump as the difference between the continuum measured at 8100 and 8400 Å, normalized to the intensity of the H1 9-3 line. We tested the following two methods to derive $T_e$.

The first one uses the pysned Continuum.BJ_HI method to generate a table of continuum jump values as a function of the temperature. Interpolation over this 1D table is then performed to obtain the temperatures from the measured continuum jump values. This requires to fix the other parameters needed to compute the continuum jump: the electron density is fixed to $10^3$ cm$^{-3}$ and the values of He$^+/H$ and He$^+/H$ are set to 0.095 and 0.005, respectively.

In the second method, the resulting jump values (obtained using the same Continuum.BJ_HI method) are interpolated over a 3D grid of $T_e$, $n_e$ and He$^+/H$ values. The grid contains 5000 randomly generated values of $T_e$, $n_e$ and He$^+/H$ in the [500–30000 K], [100–10000 cm$^{-3}$] and [0.0–1.0] ranges, respectively (we set He$^+/H = 0.12$, an-

-1°35'30"

the atomic data set contained in Table 3. For each ion, the recombination contribution correction, considering a constant 

In Fig. 9, we show the $T_e$(He i) (left panels) and $T_e$(PJ) maps using method 1 (middle panels) and method 2 (right panels) for our three objects. The $T_e$(PJ) maps derived with methods 1 and 2 are very similar, the only noticeable difference being an increasing $T_e$ in the external parts of the nebulae when using method 2, a behaviour also seen in the $T_e$(He i) maps. It is remarkable that all maps follow a very similar behaviour, with $T_e$ decreasing in the inner zones of the nebulae. This is an important result because, for the first time, low temperature zones can be directly related to high ADFs in PNe (see Section 6.3).

6 CHEMICAL ABUNDANCES

We constructed the ionic abundance maps using PYNEB and the atomic data set contained in Table 3. For each ion, the lines with the highest signal-to-noise ratios were used. As the fluxes of the triplet He i lines, such as 45876 and 47065, can be affected by the metastability of the $2^2S$ level, only the He i 46678 line was used for abundance determination because it is the brightest singlet line in the observed wavelength range. The complete list of lines considered for building the ionic abundance maps is shown in Table 6.

6.1 Ionic abundances from CELs

As described in Section 5, for each nebula a two-zone scheme was adopted, with a single $n_e$ value given by the [S ii] diagnostic ratio in the two zones, and $T_e$([N ii]) for ions with IP $\leq$ 17 eV (i.e. C$^0$, N$^0$, N$^+$, O$^0$, O$^+$ and S$^+$) and $T_e$([O iii]) for ions with IP $> 17$ eV (i.e. O$^2+$, S$^2+$, Cl$^2+$, Cl$^3+$, Ar$^2+$, Ar$^3+$ and Ar$^4+$).

In Figs. S15 to S17 of the supplementary material, we present the ionic abundance maps computed with no correction for the recombination contribution to the [N ii] 45575 and [O ii] 412520+30 CELs. In Figs. S18 to S20 of the supplementary material, the ionic abundance maps with the
recombination correction for $T_e = 4000 \text{ K}$ are shown. Accounting for the recombination contribution slightly affects the emission maps of low-ionization species in NGC 6778 and M 1–42, in particular in their central zones, where $T_e([\text{N} \text{II}])$ is significantly lower after applying the correction. In both PNe, the $[\text{O} \text{II}] \lambda 7320+30$ abundance map is the most affected one, because the recombination contribution correction have an effect on both the $T_e$ determination and the computed emissivity of the $[\text{O} \text{II}]$ lines. For HF2–2 the effect is dramatic for several lines (Fig. 7): recombination emission dominates over collisional excitation in the measured flux of the $[\text{N} \text{II}] \lambda 5755$ line, and the same happens for the $[\text{O} \text{II}] \lambda 7320+30$ lines. This translates into an extremely high $T_e$ determination in the central parts of the nebula. Given that recombination coefficients for $\text{H}^+$ have only been computed for $T_e \leq 30000 \text{ K}$ (Storey & Hummer 1995), when no recombination correction is applied, our pipeline skips the calculation of abundances in spaxels where $T_e$ exceeds this limit, hence the apparent blank gaps in the central parts of the ionic abundance maps of low ionization species illustrated in Fig. 6 of the supplementary material. This results in an apparently weird behaviour of the abundance maps. Contrarily, when the strong recombination contribution is accounted for, the abundance maps of the different low-ionization species uniformly show low abundances in the central regions of the PN and remarkably higher abundances in the necklace-like structure at the outer edge of HF2–2.

6.2 Ionic abundances from ORLs

For consistency, we built the ORL abundance maps adopting the electron temperature used for the recombination correction. We have checked that using $T_e$ diagnostics maps, such as $T_e([\text{S} \text{III}])$ or $T_e([\text{P} \text{II}])$, does not affect the spatial distribution of the abundance maps, and differences in the absolute abundance values are below 0.05 dex in $O^+ / H^+$. This is the expected behaviour, as ORL ionic abundances have a small dependence on $T_e$.

Regarding $\text{He}^+$, as the recombination coefficients by Porter et al. (2012, 2013) were only computed for $T_e \geq 5000 \text{ K}$, extrapolation to lower $T_e$ was applied according to an inverse law in $T_e$ for the emissivity of these lines. This nicely reproduces the emissivity dependence of $\text{HeI} \lambda 6678$ and $\lambda 7281$ with $T_e$ computed by Porter et al. (2012, 2013) for $T_e > 5000 \text{ K}$.

The atomic data shown in Table 3 were used to compute the $C^2+\text{, N}^2+\text{, O}^+\text{ and } O^2+\text{ abundances from ORLs, assuming case A }$ for $O^+$ and $C^2+$ and case B for $O^2+$ and $N^2+$. 2

Figs. S1 to S3 of the supplementary material clearly show that the spatial distribution of the heavy element ORL emission is concentrated in the inner regions of each nebula, and that such spatial distribution is incompatible with the CEL emission of the corresponding ions (see e.g. the $[\text{O} \text{II}]$ ORL and $[\text{O} \text{III}]$ CEL emission maps). This well-known behaviour was first addressed by Garrett & Dinerstein (2001). 2

2 For a detailed description of cases A and B, see Osterbrock & Ferland (2006).
in the PN NGC 6720 and later confirmed by several authors (e.g. Corradi et al. 2015; García-Rojas et al. 2016; Jones et al. 2016; Wesson et al. 2018). In this work, we show for the first time the spatial distribution of ionic chemical abundances from ORLs for different ions: C\(^{2+}\), N\(^{2+}\), O\(^+\) and O\(^{2+}\). We find that all of them nearly spatially coincide. This would be expected for ions with similar ionization potentials as C\(^{2+}\), N\(^{2+}\) and O\(^{2+}\) but not for O\(^+\) for which it should be seen some ionization stratification as compared to O\(^{2+}\). This result may indicate that the spatial distribution of heavy-element ORL emission would not provide information on the large scale ionization structure of the cold-gas component, but it would rather trace the distribution of unresolved nebular components where the bulk of heavy-element ORLs is produced. Each of these small structures would be (almost) optically thick to the ionizing radiation, as in some of the models presented by Yuan et al. (2011) and Gómez-Llanos & Morisset (2020), and would have its specific ionization structure.

Another parameter to explore using the O\(^+\) and O\(^{2+}\) ORL abundance maps is the ionization degree of the gas, which seems to be remarkably different when computed with ORLs or with CELs. In Fig. 10, we show the ionization degree maps for NGC 6778 traced by the O\(^{2+}\)/O\(^+\) obtained using CELs (upper left panel) and ORLs (bottom left panel), as well as the corresponding fractional uncertainties (right panels). This figure illustrates how the ORL emitting gas seems to be less ionized than the CEL emitting gas. For M 1–42 and Hf 2–2 the differences are even larger (see Figs. S21 and S22 in the online supplementary material).

The ionization of a given X\(^i\) ion into X\(^{i+1}\) is controlled by the ratio between the number of photons with energy above the X\(^i\)-ionizing energy and the number of available X\(^i\) ions to ionize. As this ratio strongly decreases in the metal-rich region because X/H is increased, the ionization into X\(^{i+1}\) decreases. In other words, the decrease in oxygen ionization in the ORL-bright region is due to an increase in the oxygen density, rather than a reduction of the hydrogen density.
density, leading to an increase of the O/H abundance. This behaviour is actually predicted by the models (see fig. 2 of Gómez-Llanos & Morisset 2020, and the related discussion).

### 6.3 The abundance discrepancy

Once the O+ and O2+ ORL abundance maps are available, the next obvious step is to build the ADF maps. This is the first time that the O+ and O2+ ADF are mapped at the high spatial resolution provided by MUSE (0.2 arcsec). Tsamis et al. (2008) built ADF maps for the high-ADF PNe NGC7090 (ADF ≈ 5, Liu et al. 1995; Fang & Liu 2011) and NGC6153 (ADF ≈ 10, Liu et al. 2000; McNabb et al. 2016) using FLAMES-ARGUS, which provided much higher spectral resolution than MUSE, but a smaller field of view (11.5 × 7.2 arcsec) and a poorer spatial resolution.

Figs. 11 to 13 present the ADF(O+) and ADF(O2+) along with their corresponding uncertainties (expressed in terms of the fractional uncertainty, i.e. ADF uncertainty/ADF) for the three PNe. The NGC6778 and M1–42 fractional uncertainty maps indicate that the uncertainties in the ADF(O2+) maps are ≤ 10 per cent in the central parts of each PN. In Hf2–2, they are larger, of the order of (20 – 30 per cent). The ADF(O+) uncertainties are significantly larger: ≥ 20 – 30 per cent in the central parts of NGC6778 and M1–42 and > 50 per cent in Hf2–2.

Figs. 11 to 13 indicate that the ADF(O2+) centrally peaks for both ions in the three objects, which is in agreement with the results previously obtained in high-ADF PNe from long-slit spectra (Corradi et al. 2015; Jones et al. 2016; García-Rojas et al. 2016; Wesson et al. 2018) and the
Table 5. Physical conditions derived for the integrated spectra.

$^a$ [Nii] 45755 line corrected for recombination contribution assuming $T_e = 4000$ K

$^b$ Colons indicates large uncertainties

The aforementioned IFU study by Tsamis et al. (2008). The ADF(O$^{2+}$) spatial distribution resembles that of the ORL O$^{2+}$/H$^+$ ratio. This is expected, with the relative homogeneity of the CEL O$^{2+}$/H$^+$ ratio in our three PNe (see Figs. S18, S19 and S20 of the online supplementary material).

This is also the first time that the ADF(O$^{2+}$) spatial distribution is presented in a PN. It is slightly different to that of ADF(O$^{2+}$), given the different spatial distribution of the O$^+$ and O$^{2+}$ abundances obtained from CELs. Even so, it clearly peaks in the inner nebular regions too, but the uncertainties are higher than for ADF(O$^{2+}$), particularly in the case of Hf2–2, where the observed O1 lines are very faint and the uncertainties in the ADF are beyond 50 per cent for the great majority of the spaxels (see Fig. 13).

6.4 Helium abundances

We first computed the total abundance maps for He. Note that no ICF is needed as its total abundance is computed by simply adding He$^+$ and He$^{2+}$. The He/H abundance maps are displayed in Fig. 15. It is clear that the total abundance is not homogeneous and there exists a positive He/H abundance gradient toward the central parts of each nebula, which is relatively mild in NGC 6778, but is much more evident in M 1–42 and Hf2–2. This points to He abundance inhomogeneities in these PNe. If two plasmas at different temperatures coexist, as proposed, the observed behaviour is consistent with the cold component being not metal-rich, but also He-enriched relative to H.

6.5 Elemental abundances from the integrated spectra

To compute the elemental abundances of elements heavier than helium, ICFs must be accounted for. The available ICFs in the literature were built using sets of PN photionization models that are theoretical representations of entire objects, in which relations between the observed and unseen ion species are obtained as a function of the ionization degree. Therefore, it does not make sense to apply these relations on a spaxel-by-spaxel basis as the observed ionization degree in a single spaxel is not representative of the whole nebula.

For this reason, the abundances of elements other than He were determined from the integrated spectrum within the mask described in Section 3.1. In Table S1 of the supplementary material (online only), we present the unreddened and extinction corrected line fluxes along with their uncertainties. The extinction corrected fluxes of [NII] 45555 and [OII] 47320+30 reported in the table correspond to a recombination correction assuming $T_e = 4000$ K. In Table 5, we show the physical conditions computed for the integrated spectra after assuming $T_e = 4000$ K for the recombination correction, and in Table 6 we show the ion abundances obtained for the different ions and emission lines.

It can be seen from Table 6 that there is an overall
good agreement between abundances derived from different lines of the same ion. The exception are the abundances from the recombination lines of C II, N II and O III, where the abundances determined from the brightest lines (C II J6462, C II J5667 and O II J4649+50) seem to be systematically higher. In the case of the O III ORLs, these differences could be attributed to C II J4649 contamination of the J4649+50 feature. McNabb et al. (2016) obtained deep high resolution spectra for M 1–42 and Hf 2–2 and did not report the detection of any of the C III lines. Similarly, for NGC 6778, Jones et al. (2016), although with lower spectral resolution, did not report the detection of any of the C III multiplet V1 lines. Hence, line contamination is unlikely to cause these systematic differences. The observed differences could also be attributed to departure from local thermodynamic equilibrium (LTE) from the upper levels of the transitions of this multiplet at the relatively low $n_e$ of these PNe. These effects were taken into account in the effective recombination coefficient computations by Storey et al. (2017), but the lack of a reliable $T_e$(OI) diagnostic precludes the computation of a reliable $n_e$ for the OII emitting plasma. Fig. 14 illustrates the dependence of the observed OII J4649+50/J4661 ratios with $T_e$ and $n_e$. To compute the O II/He II ratio for each PN, we assumed $T_e = 4.000$ K and $n_e([S II])$. It is quite clear that when fixing $T_e = 4.000$ K, the observed ratios are compatible for $n_e$ in the range $10^{3.3} \leq n_e \text{[cm}^{-3}] \leq 10^{6}$, larger than those adopted ($n_e \leq 10^{3}$ cm$^{-3}$). Regardless of the origin of these differences, we have adopted as representative values those given by the brightest line in each case, i.e. C II J6462, N II J5667 and O II J4649+50.

### 6.5.1 Ad-hoc ICFs

We considered the ICFs obtained from the literature and computed for each object from a grid of photoionization models described in Delgado-Inglada et al. (2014). We use an extended version of this grid with a larger effective temperature range and run with version c17.01 of Cloudy (Ferland et al. 2017), hold in the 3MdB_17 database\(^3\) (Morsitz et al. 2015) under the reference PNe_2020.

From the more than 700000 models in the database, we select those which fit the observed values of the following ion abundance ratios within 1 dex, for each object: H$^+/H^+$, O$^+/O^+$, S$^+/S^+$, Cl$^+/Cl^+$ and Ar$^+/Ar^+$. This set of models were used to train seven XGBoost (Chen & Guestrin 2016) regressors, using the logarithmic values of the above ion abundance ratios (scaled using the StandardScaler routine from scikit-learn) as input and the following seven ICFs: C/C$^+$, N/N$^+$, O$^+/O^+$, O$^+/O^+$, S/S$^+$ + S$^{2+}$, Cl/Cl$^+$ + Cl$^{3+}$ and Ar/Ar$^+$ + Ar$^{3+}$) as output. 80 per cent of the model set was dedicated to the training, while the remaining models were used as a test set. The hyper-parameters were set to the following values: learning rate $= 0.1$, n_estimators $= 500$ and max_depth $= 10$, which give a standard deviation of less than 1 per cent for the difference between the predicted and test values in the test set. This process was applied for each object separately.

These ad-hoc ICFs were then used to determine the elemental abundances in each object and to compare the results with the values obtained using the ICFs from Peimbert & Costero (1969), Kingsburgh & Barlow (1994) and Delgado-Inglada et al. (2014). The abundances are listed in Table 7.

Comparison between the ICFs obtained using ML techniques and those from the literature results in elemental abundances that are in excellent agreement for all cases (within 0.04 dex at most), except for N in Hf 2–2. For this PN, the ICF computed using ML provides $12 + \log(N/H) = 8.14 \pm 0.18$, while the classical ICF (N/O$=N^+/O^+$, e.g. log(ICF(N$^+/O^+$)) = 0.0) yields 7.83 $\pm$ 0.28. However, even in this case, the difference is still within 1-$\sigma$. For Hf 2–2, the He ionization is rather low (He$^+/He^+$ + He$^{2+}$ $\sim 0.01$) and this classical ICF is not correct (see panel (a) of fig. 6 in Delgado-Inglada et al. 2014). Our ad-hoc ML method leads to log(ICF(N$^+/O^+$)) $= 0.31 \pm 0.05$ dex. The values from Delgado-Inglada et al. (2014) are 0.12$^{+0.46}_{-0.26}$ when He$^+$ is seen, and 0.52$^{+0.40}_{-0.26}$ instead, enclosing our ML value.

The ICFs needed to obtain the final element abundances are mainly based on ion fractions of He and O when derived from Delgado-Inglada et al. (2014), and ion fractions

\(^3\) See full description at https://sites.google.com/site/mexicanmillionmodels/the-different-projects/pne_2014

\(^4\) We have used the ICFs from Delgado-Inglada et al. (2014) for He (eq. 10), C (eq. 39), O (eq. 12), S (eq. 26), Cl (eq. 29) and Ar (eq. 35), and from Peimbert & Costero (1969); Kingsburgh & Barlow (1994) for N.
of He$^{2+}$/He$^+$, O$^{2+}$/O$^+$, S$^{2+}$/S$^+$, Cl$^{3+}$/Cl$^{2+}$, and Ar$^{3+}$/Ar$^{2+}$ in the case of our ad-hoc ICFs from ML. The metal ionization states are obtained from CELs, but for helium we rely on RLs, without a clear knowledge of where these lines are coming from. If a significant proportion of helium lines originate from the “cold” region with a different ionization state than the “warm” region, the ICFs depending on He$^{2+}$/He$^+$, and the corresponding abundances, may be wrong.

6.5.2 Comparison with previous works
The most relevant previous works are those by Jones et al. (2016) for NGC 6778, Liu et al. (2001) and McNabb et al. (2016) for M 1–42 and Liu et al. (2006) and McNabb et al. (2016) for Hf 2–2. Table 7 presents the elemental abundances obtained from the integrated spectra of the three PNe in this work as well as those reported in the literature.

Ideally, comparison of chemical abundances obtained from different data sets should be done by recomputing abundances using the same methodology. However, this is not always an easy task, especially given the limited wavelength coverage of the MUSE data, that miss some important lines at wavelengths bluer than 460 nm (e.g. [O ii] λ4336+29 and [O iii] λ4363). Therefore, we have decided to carry out a critical comparison of the most relevant elemental abundances.

For NGC 6778, there are significant differences between our abundances and those derived by Jones et al. (2016), with the exception of O from RLs and N from CELs, which are largely consistent. We find an excellent agreement in the integrated spectra of NGC 6778 and M 1–42, owing to the fact that the auroral [S ii] λ6312 line is relatively weak in this PN. However, after examination of the observed [S ii] line fluxes relative to Hβ in the two previous works, we find that Liu et al. (2006) reported a [S ii] λ6312/Hβ ratio that is 60 per cent higher than the reddened flux measured in this work from the integrated spectrum. Unfortunately, these authors did not cover wavelengths redder than 720 nm, and hence they were unable to detect the nebular [S ii] lines.

The fluxes reported by McNabb et al. (2016) are deemed unreliable owing to two main reasons: i) they reported fluxes one order of magnitude higher for multiple faint lines, which points to some kind of mistake in transcribing the line flux tables; ii) the dereddened fluxes of the H1 Paschen lines are much brighter (more than a factor 2) than expected for the assumed physical conditions, while the [S ii] λ4900/Hβ line ratio is ≈ 30 per cent smaller than observed here, which points to problems with the flux calibration, extinction correction and/or telluric absorptions.

6.5.3 Effect of the recombination contribution correction on the integrated spectra
We have investigated the effect of neglecting the recombination contribution correction on the integrated spectra. Although its effect on the physical conditions maps is dramatic, as we have shown in Section 5.2, it is somewhat mitigated in the integrated spectra of NGC 6778 and M 1–42, owing to the different weights of the ORL and CEL emitting zones in the integrated spectrum. However, it is still extremely significant in Hf 2–2 and should be accounted for carefully. We find a recombination contribution to the [N ii] λ4555 auroral line of ≈ 17, ≈ 18 and ≈ 64 per cent (assuming $T_e = 4000$ K) for NGC 6778, M 1–42 and Hf 2–2, respectively. This translates into respective $T_e([N ii])$ decreases of ≈ 550, ≈ 600 and ≈ 3950 K in NGC 6778, M 1–42 and Hf 2–2, which are subsequently propagated to the abundances of low-ionization species. Similarly, these corrections are of ≈ 44, ≈ 42 and ≈ 75 per cent for the [O ii] λ4363 auroral line in the three PNe under the same $T_e$ conditions. This illustrates the importance of accounting for the recombination contribution when these lines are the only ones available to compute the O$^+$ abundances.

\(^c\) In these cases, the ICFs were not computed using machine learning techniques given the lack of ionization state diagnostics for the “cold” gas component. Instead, we used the ICFs from Delgado-Inglada et al. (2014): C (eq. 39) and O (eq. 12). However, these recipes should be taken with caution (see text). The influence of a cold region on the HI emission lines is not taken into account here (see Section 7.1).

7 DISCUSSION

7.1 On the influence of a cold region on HI temperature and abundance determinations

The main result of our analysis of the emission lines, that led to the determination of the physical and chemical parameters of the three PNe, points to the presence of two phases of gas, one of which is quite cold \((T_e < 8000 \text{ K})\). This cold region shows metal abundances significantly larger than those obtained for the “classical” region. Despite being poor in hydrogen, the cold region may substantially contribute to the observed HI recombination line and continuum emission (this is clearly the case considering the low temperatures from the Paschen jump obtained in Section 5.3). This opens an interesting discussion as to the way ionic (and elemental) abundances are derived. Let us consider a given emission line at wavelength \(\lambda\) emitted by the two different phases of the gas (the warm “classical” region and the cold, metal-rich region), identified by the \(c\) and \(w\) superscripts, respectively. The resulting line intensity, normalized to HI, is the following:

\[
\frac{I_{\lambda}}{I_{\lambda}} = \frac{I_{\lambda}^{w} + I_{\lambda}^{c}}{I_{\lambda}^{w} + I_{\lambda}^{c}} = \frac{I_{\lambda}^{w} + I_{\lambda}^{c}}{(1 - \omega)I_{\lambda}^{w} + \omega I_{\lambda}^{c}},
\]

where \(\omega\) is the weight of the cold region in the total HI (and

Figure 16. Contour plot of the observed Paschen jump electron temperature as a function of the temperature of the cold region and its relative weight in the total HI emission. For the warm gas, we assumed \(T_e = 8000 \text{ K}\). The red diamond illustrates the case of a cold region at 800 K contributing 3.3 per cent of the emission and leading to an apparent Paschen jump temperature of 4000 K.
recombination continuum) emission (the “classical” region contribution being $1 - \omega$). The abundance of the ion responsible for the line emission is commonly determined assuming it is directly proportional to $I_x/I_H$. If the line is only emitted by one of the two regions, this method will underestimate the ion abundance. However, if it is emitted by the warm region alone (as is the case for CELs), $I_x = 0$ and the abundance should be obtained from $I_x/I_H = I_x/(1 - \omega)I_H$. The abundance is underestimated by a factor $1/(1 - \omega)$. In the case of a line only emitted by the cold region (e.g. ORLs), the underprediction factor is $1/\omega$.

Under this hypothesis of two distinct gas phases, the ionic abundances in each region can be computed using the corresponding electron temperature. For the “classical” region, it is obtained using “classical” diagnostic line ratios like $\text{[OIII]}$ 4363/45007. For the cold region, the exact value of the temperature is commonly considered as not necessary, as the emissivities of the metal and H recombination lines have almost the same dependence on the temperature and cancel each other in the abundance determination. However, H I emission is produced in both regions, and therefore this argument no longer applies.

The weight $\omega$ of the cold region in the total Hβ emission can be estimated using the determination of the temperature from the Paschen jump (see Section 5.2.1), in a way inspired by Gómez-Llanos & Morisset (2020). In Fig. 16 we show the apparent Paschen jump temperature determined from an observation where the emission of the continuum and of the H I lines results from emission in both a warm region (here at $T_e = \sim 8000$ K) and a cold region of temperature $T_c$ (x-axis). The y-axis is the cold region weight $\omega$. We see that if the cold region is, for example, at 800 K, an apparent Paschen jump temperature of 4000 K is obtained if the cold region contribution to H I is as small as 3.3 per cent (red diamond in Fig. 16). This implies that any determination of abundances obtained from emission lines mainly emitted by the cold region needs to be corrected by a factor of $1/0.033 = 30!$ The determination of the abundances from CELs will only be underestimated by a factor $1/(1 - 0.033)$, that is, $\sim 3.4$ per cent. This obviously depends on the adopted values for the warm and cold region temperatures. In addition, the H I temperature may not be relevant to obtain the cold region temperature if strictly metal-rich (and then H- and He-poor).

We can then derive a correction to the ionic abundances and obtain a more realistic value of e.g. $O^{2+}/H^+$ in the cold and warm regions. The ratio between these corrected abundances obtained from ORLs and CELs is close to what Gómez-Llanos & Morisset (2020) refer to as the Abundance Contrast Factor (ACF). The relation between the ACF and the observed ADF is:

$$\text{ACF}(X^{i+} / H^+) = \text{ADF}(X^{i+} / H^+)_\text{rec} \cdot \frac{1 - \omega}{(X^{i+} / H^+)_\text{col}} \cdot \frac{1 - \omega}{\omega} = \text{ADF}(X^{i+} / H^+) \cdot \frac{1 - \omega}{\omega} \cdot \text{ACF}(X^{i+} / H^+).$$

(4)

We explore the effect of the “dual phase hypothesis” on the determination of the ACF($O^{2+}/H^+$) as defined by Eq. 4 for our three PNe. We consider three different values for the cold region temperature: 500, 800 and 1000 K. The obtained ADF does not significantly change when $T_c$ varies from 8000 to 12000 K, and hence we fix the electron temperature of the warm phase to $T_w = 8000$ K. Table 9 gives the logarithmic ADF($O^{2+}/H^+$) and ACF($O^{2+}/H^+$) values that we obtain for each PN. In the case of PN Hf 2/2, where the Paschen jump temperature is close to 1000 K, $T_c \approx 500$ K is preferred. We can see that the ACF increases for decreasing $T_c$. For NGC 6153, Gómez-Llanos & Morisset (2020) determined log(ACF($O/H$)) in the range 2.1 – 2.7 dex, with $T_c$ close to 500 K. These values are very similar to the ones obtained here. It is interesting to note that the highest ACFs are not obtained for the highest ADFs, which points to both parameters not being connected by a simple relation.

Ueta & Otsuka (2021) point out the effect of considering the “true” $T_f$ in the definition of the expected H I line ratio when determining the extinction coefficient from 2D data. We use 10 000 K to compute the emissivities of the H I lines and obtained the classical value of 2.86 for Hα/Hβ. However, we have already described that part of the H I emission originates from a much colder region, which can increase this ratio to values up to 3.05 (equivalent to the theoretical Hα/Hβ ratio obtained for $T_f = 4500$ K). We thus reran the whole pipeline to derive all the results presented in previous sections using this larger value of Hα/Hβ (then reducing the reddening correction). We found that the [N II] and [S II] electron temperatures decrease by 100 and 200 K, respectively, and an increase of the metal abundances by 0.02 to 0.07 dex, depending on the wavelength of the emission line. We also carried out a quick, more detailed exploration on the effects introduced in our computations of physical conditions and chemical abundances by using the spatial variations of $T_c$ (PI) to compute the resolved c(Hβ), and found no strong effect. Therefore, the main conclusions presented in previous sections remain unaltered.

### 7.2 Oxygen content in the cold region

Following Gómez-Llanos & Morisset (2020), we can estimate the oxygen mass ratio between the cold and the warm region, $\frac{M_c}{M_w}$. Considering that the oxygen ORLs are only emitted by the cold region and that the CELs come from the warm region, we have:

$$\frac{M_c}{M_w}(O^+)= \frac{\epsilon_{OII}(T_c^\epsilon, n_e^\epsilon)}{\epsilon_{OII}(T_w^\epsilon, n_e^w)} \cdot \frac{I_{OII}}{I_{OII}} \cdot \frac{n_e^w}{n_e^\epsilon}$$

(5)

| Table 9. Logarithmic ADF($O^{2+}/H^+$) and ACF($O^{2+}/H^+$) values for the collapsed spectra. |
|---------------------------------|---------------|---------------|---------------|
|                                | NGC 6778      | M1–42         | Hf 2–2        |

and

$$\frac{M^w I}{M^w II} = \frac{\epsilon_{OIII}(T^w, n_e^w)}{\epsilon_{OII}(T^w, n_e^w)} \cdot \frac{T_{OII}}{T_{OIII}} \frac{n_e^w}{n_e^w},$$

(6)

where $\epsilon$ is the emissivity corresponding to the observed intensity $I$. The results are presented in Table 10. The values of $M^w I$ are inversely proportional to the adopted $T_e^w$ and almost linearly dependent on the adopted $T_e^w$, with both parameters being highly uncertain. We used $T_e^w = 800$ K; higher temperatures (e.g. 4000 K) would result in larger oxygen mass ratios by a factor of about 4. The oxygen mass fraction does not vary significantly from one object to another and is similar to the value obtained by Gómez-Llanos & Morisset (2020) for NGC 6153 considering $T_e^w = 800$ K. Whatever the exact value of $T_e^w$, we found that the amount of oxygen contained in the cold and “classical” warm regions are of the same order of magnitude.

We show in this Section and Section 7.1 that a better knowledge of the properties of the three PNe presented here requires a good determination of either the chemical composition or the electron temperature of the metal-rich, cold region. We remind that the ADF does not provide any insight into the actual enrichment of the cold region. A detailed photoionization model, as the one obtained by Gómez-Llanos & Morisset (2020), could be obtained by exploring large grids of photoionization models, varying O/H and the weight of the rich region, as well as its density and helium abundance. This is far beyond the scope of the present work, but is certainly necessary to place constraints on the physical and chemical properties of high-ADF PNe. More observational constraints, such as high spectral and spatial resolution observations that provide O II ORL electron temperature and density diagnostic ratios, will also be helpful.

7.3 The link between high ADF and binarity

It now seems relatively clear that the extreme ADFs observed in some PNe are due to the presence of a second, metal-rich gas phase (e.g.: Liu et al. 2006; Wesson et al. 2018). The origin of this second gas phase is highly uncertain and without knowledge of the properties of the two phases (which cannot be inferred directly from observations; Gómez-Llanos et al. 2020; Gómez-Llanos & Morisset 2020), various (highly speculative) hypotheses that have been put forward in the literature.

It has been highlighted the similarities between the observed ORL abundances and those in neon novae (e.g. Wesson et al. 2003, 2008a), leading to speculation that the metal-enriched phase could be the product of some form of late reprocessing either as a result of mass transfer from a companion star to the white dwarf (Wesson et al. 2008b; Jones et al. 2019) or fallback of binary common-envelope material (Kuruwita et al. 2016; Reichardt et al. 2019). Wesson et al. (2018) argued in favour of a nova-like origin of the metal-enriched material, that may be strongly linked to the correlation between short binary orbital periods and high ADFs. In either case, the material ejected due to this reprocessing would be expected to have an appreciably larger expansion velocity than the “normal” nebular phase due to earlier mass loss. While some evidence exists for kinematic differences between the ORL and CEL emitting gas phases in PNe (Richer et al. 2017), nova-like velocities have not been detected so far in the H-deficient material in any high-ADF PNe. Unfortunately, the spectral resolution of our MUSE data is insufficient to discern any kinematic differences between the O II and [O III] emitting material. Thus, detailed 2D kinematic studies of both gas components are still needed to address any solid conclusions.

The possibility that the link between extreme ADFs and common-envelope explosion is simply a consequence of the conservation of chemical stratification in the giant’s envelope upon ejection should also be considered. While the ORL emitting gas is more centrally located in all the PNe analysed in this work, its spatial distribution (and that of the ADF, see Figs. 11, 12 and 13) varies relatively smoothly rather than appearing as a clearly distinct shell. The extremely short time-scale of the common envelope (~ 1 yr, e.g. Igoshev et al. 2020), as well as the limited mixing of the envelope over this time-scale (due to its strong entropy and density gradient; Webbink 2008), could mean that the chemical stratification in the envelope is preserved upon ejection. In that case, the centrally peaked ADF and the distribution of the CEL-emitting material may simply be a consequence of this chemical stratification, whereby the internal parts of the giant’s envelope are richer in the products of nucleosynthesis, and hence have a naturally higher metallicity. This allows the inner parts to cool more efficiently and leads to enhanced ORL emission.

8 CONCLUSIONS

In this work we present deep integral-field unit (IFU) spectroscopy of three PNe (NGC 6778, M 1–42 and Hf 2–2) with previously reported high abundance discrepancy factors (ADF > 20). The spectra were obtained with the MUSE spectrograph covering the wavelength range 4600 – 9300 Å with effective spectral resolution from $R = 1600$ to $R = 3500$ for the bluest to the reddest wavelengths, respectively. The analysis is restricted to the central 900 arcsec$^2$ in NGC 6778 and M 1–42 and the central 1600 arcsec$^2$ in Hf 2–2 with a spatial sampling of 0.2 arcsec. These are the deepest IFU data for the three PNe currently available.

We produced emission line maps of more than 40 lines for each object, including several recombination lines of H$, H^+$, He$^+$, He$^{2+}$, C$^{2+}$, N$^{2+}$, O$^{+}$ and O$^{2+}$ and collisionally excited lines of C$^0$, N$^0$, N$^+$, O$^0$, O$^+$, O$^{2+}$, S$^+$, S$^{2+}$, C$^{+}$, C$^{2+}$, C$^{3+}$, A$^{2+}$, Ar$^{2+}$ and Ar$^{3+}$. From these we compute the extinction, physical conditions ($T_e$ and $n_e$) from CEL and ORL diagnostics and ionic abundance maps using machine learning tech-
niques, which significantly reduce the computational time needed to analyse such large data sets.

We find that the recombination correction plays a very important role in both the $T_e([\text{N} \text{II}])$ and $O^+$ abundance maps. In addition, the obtained maps strongly depend on the assumed $T_e$ for the recombination emission. We applied the recombination correction to the auroral [N II] $\lambda 6575$ and [O II] $\lambda 3729+30$ CELs assuming $T_e=1,000, 4,000, 8,000$ K, as well as no correction at all. We find that adopting a recombination correction assuming $T_e=4,000$ K is a good compromise for the PNe presented in this work, given the similarity with what is obtained for their central parts using recombination line $T_e$ diagnostics. We built CEL ionic abundance maps adopting different recombination contributions to the auroral [N II] and trans-auroral [O II] lines, showing that the ionic abundance maps of low-ionization species are strongly affected if this contribution is not properly taken into account. The H I continuum to line ratio and the He I line ratio maps show $T_e$ values systematically lower than those obtained from CEL diagnostics. Furthermore, both types of map display very similar structures, the most remarkable being a decrease of $T_e$ toward the inner zones of the PNe, which is found to correlate with an enhancement of the ORL emission lines of heavy elements.

We computed elemental abundances using the integrated spectra of each PN and a large number of ionization constraints, such as $\text{He}^{+}/\text{He}$, $O^+/O^+$, $S^+/S^+$, $\text{Cl}^+/$Cl$^+$, and Ar$^+/\text{Ar}^+$, from which ad hoc ICFs are calculated using a large database of photoionization models and machine learning methods. For all the elements considered and objects, the agreement with the ICFs from the literature is excellent, with the exception of N in H II-2, where 0.3 dex differences are found.

From the ionic abundance maps of the C II, N II, O I and O II ORLs we find that ORL emission concentrates at the inner regions of the three PNe compared to the CEL emission of the same ion. This points to the ORL emission of heavy elements coming from a different plasma component than the CEL emission. We also find a significant decrease of the degree of oxygen ionization in the ORL emitting gas relative to the “normal” gas component, implying that the increase of the O/H abundance may be the result of the increase of the oxygen density rather than a decrease of the hydrogen density, in agreement with recent photoionization model results by Gómez-Llanos & Morisset (2020). We have also constructed, for the first time in photoionized nebulae, the ADF maps of O$^+$ and O$^{2+}$. In both cases, the ADF clearly peaks centrally for the three PNe.

All these results strongly support the “bi-abundance” model of high-ADF PNe, which stands for the presence of two gas phases, one cold ($T_e=10^3$ K) and metal-rich that is responsible for the bulk of heavy element ORL emission, and a warm one ($T_e=10^4$ K) where the heavy element CEL emission is produced.

Under this dual gas hypothesis, we show that the main issue with the derivation of the ionic abundances of metals from either ORLs or CELs is the determination of the contribution of each gas component to the observed H I emission. We therefore present a method to estimate the relative contribution of the two gas phases to the total ionic abundances when their physical conditions and the $T_e$(H I) are known, allowing to compute corrections to the abundances derived from ORLs or CELs. We find that these abundance corrections strongly depend on the adopted values for the warm and cold region temperatures.

Using reasonable values for the undetermined parameters (electron temperature and density, and ionization of the cold region), we derive the O$^+/H$ contrast between the warm and cold regions (known as the ACF, which is significantly higher than the ADF, see Gómez-Llanos & Morisset 2020) and the oxygen mass ratios between the two regions. We conclude that the amount of oxygen in the cold region is of the same order of magnitude as in the warm region.

Finally, we conclude that the binary origin of the metal-rich phase can only be unravelled with detailed spatially resolved kinematics of both gas components. However, we speculate with the possibility that the conservation of chemical stratification in the giant’s envelope upon ejection can be a reasonable explanation for the link between extreme ADFs and the common envelope evolution.

DATA AVAILABILITY

The raw MUSE data are available from the ESO archive facility at http://archive.eso.org/. The data products used in this paper: reduced data cubes, extracted emission line maps, analysis pipeline and its outputs, are available from the authors under reasonable request. The emission line maps and the PYTHON scripts used for the analysis and to produce the tables and figures presented in this paper are available at https://github.com/Morisset/MUSE_PNe.

ACKNOWLEDGEMENTS

This paper is based on observations made with ESO Telescopes at the Paranal Observatory under program IDs 081.D-0857 and 097.D-0241. We want to thank the referee, Prof. R. B. C. Henry, for a prompt evaluation of the paper. JG-R and CM would like to thank Grazyna Stasińska and Ana Monreal-Ibero for valuable discussions. We also thank Angel R. López-Sánchez for his help in the preparation of Figure 1. JG-R acknowledges support from the Severo Ochoa excellence programs SEV-2015-0548 and CEX2019-000920-S, from the State Research Agency (AEI) of the Spanish Ministry of Science, Innovation and Universities (MCIU) and the European Regional Development Fund (FEDER) under grant AYA2017–83383–P and from the Canarian Agency for Research, Innovation and Information Society (ACIISI), of the Canary Islands Government, and the European Regional Development Fund (ERDF), under grant with reference ProDI201010074. JG-R, DJ and RC acknowledge support under grant P/208614 financed by funds transferred from the Spanish Ministry of Science, Innovation and Universities, charged to the General State Budgets and with funds transferred from the General Budgets of the Autonomous Community of the Canary Islands by the MCIU. CM acknowledges support from grant UNAM / PAPIIT – IN101220 and from a visitor grant to the IAC under the Severo Ochoa excellence program CEX2019-000920-S. DJ acknowledges support from the Erasmus+ program of the European Union under grant number 2020-1–CZ01-KA203-078200. HM acknowledges the use of the comput-
ing facilities available at the Laboratory of Computational Astrophysics of the Universidade Federal de Itajubá (LAC–UNIFEI). The LAC–UNIFEI is maintained with grants from CAPES, CNPq and FAPEMIG. In particular, grants APQ–1305–17 and CNPq 436117/2018–5. This research made use of Astropy5, a community-developed core Python package for Astronomy (Astropy Collaboration et al. 2013, 2018). The paper has been edited using the Overleaf facility.
