Abstract
Rationale Depression and anxiety are common symptoms in Parkinson's disease for which there are no optimal treatments. Sarizotan, an agonist at serotonin receptors and partial agonist at dopamine D2-like receptors, has shown antidyskinetic effects in Parkinson's disease. Based on its pharmacological profile, we hypothesized that sarizotan could also have antidepressant-like properties.

Objectives Examine effects of sarizotan on behavioral and histological measures known to be regulated by established antidepressants in normal and unilaterally 6-hydroxydopamine-lesioned rats.

Results Sarizotan was found to significantly reduce immobility in the modified forced swim test, a measure of antidepressant-like activity, but had no effects on thigmotaxis or corner time, measures of anxiety-like behavior, in the unilaterally 6-hydroxydopamine-lesioned rats. At the same dose, sarizotan counteracted L-DOPA/benserazide-induced supersensitized rotational behavior and dyskinesias without significantly affecting L-DOPA/benserazide-induced locomotion. At the histological level, sarizotan alone or in combination with L-DOPA/benserazide stimulated cell proliferation, measured by bromodeoxyuridine incorporation or Ki-67 staining, both in the subgranular zone of the dentate gyrus and in the subventricular zone of the striatum in the 6-hydroxydopamine-lesioned hemisphere. Likewise, combined sarizotan and L-DOPA/benserazide treatment stimulated doublecortin levels in the subgranular zone of the dentate gyrus.

Conclusions These significant effects of sarizotan in the modified forced swim test and on cell proliferation are reminiscent of those found after various antidepressant therapies. These data suggest that sarizotan may have some antidepressant-like and restorative properties in Parkinsonism.

Keywords 6-hydroxydopamine · Parkinson's disease · Bromodeoxyuridine · Ki-67 · Doublecortin · Serotonin · Modified forced swim test

Introduction
Sarizotan was developed as a putative atypical antipsychotic agent and exhibits high affinities to serotonin 5-HT1A receptors and dopamine D1>D3>D2 (i.e., D2-like) receptors with the profile of a 5-HT1A receptor agonist and D2-like receptor partial agonist (Bartoszyk et al. 2004). Studies in animal models of Parkinsonism revealed that sarizotan has antidyskinetic properties and could represent a new approach for the treatment of extrapyramidal motor complications in Parkinson's disease (PD). Indeed, when sarizotan was systemically administered alone or together with 3,4-dihydroxy-L-phenylalanine (L-DOPA) to rats rendered Parkinsonian by unilateral 6-hydroxydopamine (6-OHDA)-lesioning or to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated nonhuman primates, it attenuated the shortening in motor response duration and choreiform dyskinesias induced by chronic L-DOPA treatment (Bibbiani et al. 2001). These antidyskinetic effects of sarizotan occurred without any effects on Parkinsonian severity or on the antiparkinsonian response to L-DOPA.
However, the human studies on the antidyskinetic effects of sarizotan have not been conclusive (Bara-Jimenez et al. 2005; Goetz et al. 2007).

Depression and anxiety are common non-motor symptoms in PD (Chaudhuri et al. 2006). Despite the high incidence of these co-morbidities in PD, there are no optimized treatments for these conditions. It is known that 5-HT\textsubscript{1A} receptors are critically involved in the regulation of mood and emotionality and are thought to mediate some therapeutic actions of established antidepressants including selective serotonin reuptake inhibitors (SSRIs) (see, e.g., Savitz et al. 2009). Moreover, SSRIs, tricyclic antidepressants, and electroconvulsive shock therapy, all increase post-synaptic 5-HT\textsubscript{1A} receptor signaling through direct or indirect effects (Savitz et al. 2009). Thus, based on its stimulatory properties of 5-HT\textsubscript{1A} receptors, sarizotan could exert antidepressant and anxiolytic actions.

5-HT\textsubscript{1A} receptor knockout mice display increased anxiety-related behavior, which cannot be rescued by antidepressant drug treatment (Ramboz et al. 1998). Moreover, 5-HT\textsubscript{1A} receptor knockout mice are insensitive to the neurogenic effects of fluoxetine, a commonly prescribed antidepressant and SSRI (Santarelli et al. 2003). Likewise, selective antagonism at 5-HT\textsubscript{1A} receptors decreases cell proliferation (Radley and Jacobs 2002) and, vice versa, stimulation of 5-HT\textsubscript{1A} receptors increases cell proliferation (Baner et al. 2004). Interestingly, the numbers of proliferating cells in the subventricular zone (SVZ) of the striatum and in the subgranular zone (SGZ) of the dentate gyrus are reduced in post-mortem brains of individuals with PD (Hoglinger et al. 2004). Such reductions could also be found in experimental Parkinsonism in rodents and restored by treatment with L-DOPA or selective agonists at D\textsubscript{2}-like receptors (Hoglinger et al. 2004; Yang et al. 2008), with no mention of effects of 5-HT receptor ligands.

The hypotheses underlying the present study were that sarizotan, due to its pharmacological profile, may exert antidepressant- and/or anxiolytic-like behavioral effects and stimulate cell proliferation in neurogenic brain regions in experimental Parkinsonism. We therefore used both normal and unilaterally 6-OHDA-lesioned rats and examined the behavioral effects of sarizotan in the modified forced swim test (mFST), a measure of antidepressant-like activity, and on thigmotaxis or corner time, measures of anxiety-like behavior. For comparison, behavioral effects of saline, sarizotan, or L-DOPA/benserazide alone, or in combination, on rotations, abnormal involuntary movements (AIMs) and motor activity were measured in the unilaterally 6-OHDA-lesioned rats. We also examined cell proliferation and neurogenesis in the neurogenic brain regions, SVZ and SGZ, in unilaterally 6-OHDA-lesioned rats chronically treated with saline, sarizotan, or L-DOPA/benserazide alone or in combination. Bromodeoxyuridine (BrdU), an exogenous compound which incorporates into the DNA of dividing cells, and Ki-67, an endogenous protein expressed only during mitosis, were used to measure cell proliferation. Doublecortin (DCX), a protein present in immature neurons, was used to measure neurogenesis.

Materials and methods

Animals, surgery, and pharmacological treatment

Male Sprague–Dawley rats (150 g; Scanbur, Sweden) were used for this study and housed in separate air-conditioned rooms (12-h dark/light cycle) at 20°C and a humidity of 53%. Experiments were performed in agreement with the European Communities Council Directive of 24 November 1986 (86/609/EEC) on the ethical use of animals and were approved by the local ethical committee at Karolinska Institute.

In most of the experiments, unilaterally 6-OHDA-lesioned rats were used to mimic aspects of Parkinsonism. Unilateral 6-OHDA lesioning of nigral dopaminergic axons was performed as previously described (Zhang et al. 2008). Briefly, rats were anesthetized with ketamine (80 mg/kg, i.p.; Parke-Davis, Boxmeer, Netherlands)/xylazine (10 mg/kg, i.p.; Bayer, Kiel, Germany), pretreated with desipramine (25 mg/kg, i.p.; Sigma, Stockholm, Sweden) and pargyline (5 mg/kg, i.p.; Sigma), placed in a stereotoxic instrument and injected with 6-OHDA (2.5 μl of a 5 mg/ml solution; Sigma) into the medial forebrain bundle of the right hemisphere (AP −2.8 mm, ML −2.0 mm and V −9.0 mm). Two weeks after unilateral 6-OHDA lesioning, rats were administered with apomorphine (1 mg/kg, i.p; Sigma), and their contralateral rotations were measured over 30 mins. Only rats which rotated contralaterally more than 100 times were included in further experiments. The rats were then equally distributed in groups based on apomorphine-induced rotations for the subsequent experiments. The efficacy of the dopamine denervation was verified post-mortem by measurements of the striatal levels of tyrosine hydroxylase (TH) and dopamine transporter (DAT). Four weeks after the surgery, the animals were used for the experiments. 6-OHDA-lesioned rats were treated with saline (n = 15), and sarizotan (1 mg/kg, n = 6 and 2.5 mg/kg, i.p.; Merck KGA, n = 16) in the acute experiments studying mFST and motor activity. We also used normal rats which were treated with saline (n = 6) and sarizotan (1 mg/kg, n = 6 and 2.5 mg/kg, i.p.; Merck KGA, n = 6) in these acute behavioral experiments. In the chronic experiments studying rotation, AIMs, motor activity, cell proliferation, and neurogenesis, 6-OHDA-lesioned rats were treated with saline (n = 4), sarizotan (2.5 mg/kg, i.p., n = 5), L-DOPA/
Benserazide (10/7.5 mg/kg, i.p., Sigma, n=9) alone, or sarizotan (2.5 mg/kg, i.p.)+L-DOPA/benserazide (10/7.5 mg/kg, i.p., n=5) in combination. Throughout these studies, the methyl ester form of L-DOPA was used. The choices of dosages of sarizotan and L-DOPA were based on previous experiments (Bibbiani et al. 2001; Lundblad et al. 2004). At the end of the chronic experiment, the rats were anesthetized (see above) and perfused (intracardially with 4% paraformaldehyde) 2 h after the last injection.

Behavioral experiments

**MFST to measure antidepressant-like activity**

We used the mFST (Lucki 1997), which, in comparison to Porsolt's original test (1977), does not allow the rats to balance on their tails. It is a 2-day procedure, and we studied both normal and unilaterally 6-OHDA-lesioned rats. (The 6-OHDA-lesioned rats were equally distributed in groups based on apomorphine-induced rotations in 30 min (saline 137.6±15.7; sarizotan (1 mg/kg) 145.8±12.9; sarizotan (2.5 mg/kg) 139.2±15.1)). On the first day, the rats were gently placed individually in a vertical Plexiglas cylinder (height 45 cm, diameter 19 cm) filled with 26°C water at a depth (35 cm) that makes it impossible for the rat to reach the bottom with hind paws. The animals were removed from the water after 15 min and dried before they returned to their home cages. The water was changed after each session. On the second day, the rats were placed in the same cylinders for 5 min, 30 min postinjection of saline or sarizotan (1 mg/kg and 2.5 mg/kg, i.p.). The presented data are pooled from two experiments. In one experiment, six animals were used in each studied group. In another experiment, only unilaterally 6-OHDA-lesioned rats treated with saline (n=9) or sarizotan (2.5 mg/kg; n=10) were examined. The data for the latter two groups were similar between the two experiments and therefore it was justified to pool them.

**Thigmotaxis and corner time to measure anxiety-like activity**

Thigmotaxis and corner time in an open-field measure the conflict of an animal to enter open spaces and reflect anxiety-like responses. Square open-field arenas (680×680×450 mm) were used to measure thigmotaxis and corner time (Ericson et al. 1991). The arenas were equipped with two rows of photocells, sensitive to infrared light, placed 40 and 125 mm above the floor. The photocells were spaced 90 mm apart, and the last photocell in a row was spaced 25 mm from the wall. The open field was enclosed in a ventilated and sound-attenuating box. The variables recorded were horizontal activity (all interruptions of photo beams in the lower rows), peripheral activity (all interruptions of photo beams in the lower rows closest to the walls), and time spent in the corners of the boxes. Thigmotaxis is the ratio between peripheral and horizontal activities. These studies were performed only unilaterally 6-OHDA-lesioned rats and measurements were done for 10 min, 35 min postinjection of saline (n=4), sarizotan (n=5, 2.5 mg/kg, i.p.), L-DOPA/benserazide (n=9, 10/7.5 mg/kg, i.p.) alone, or sarizotan (2.5 mg/kg, i.p.)+L-DOPA/benserazide (10/7.5 mg/kg, i.p., n=5) in combination acutely or after 24 days of treatment. (The 6-OHDA-lesioned rats were equally distributed in groups based on apomorphine-induced rotations in 30 min (saline 210.3±41.0; sarizotan 199.6±38.5; L-DOPA/benserazide 239.9±35.9; sarizotan+L-DOPA 232.4±42.7).

**Measurements of rotations, AIMs, and motor activity**

Measurements of rotations, AIMs, and motor activity were performed sequentially in the same animals acutely and after 24 days of treatment (and are identical to the animals used for studies of thigmotaxis and corner time). For measurements of rotations and AIMs, unilaterally 6-OHDA-lesioned rats were treated with saline (n=4), sarizotan (n=5), L-DOPA/benserazide (n=9) alone, or sarizotan+L-DOPA/benserazide (n=5) in combination and placed in individual cages. The number of ipsilateral and contralateral rotations was thereafter counted for 30 min on days 1 and 24 to measure rapid responses to L-DOPA, which are known to supersensitize after chronic L-DOPA administration (Bibbiani et al. 2001). Immediately after the quantification of rotational behaviors, the incidence of AIMs was scored for 5 min (Zhang et al. 2008). This procedure was adapted from a validated rodent scale (Lundblad et al. 2004). The AIMs were classified into four subtypes: Forelimb, Orofacial, Axial, and Locomotive behaviors. Enhanced manifestations of normal behaviors such as grooming, gnawing, rearing, and sniffing were not included in the rating. The severity of each AIM subtype was assessed using scores from 0 to 4 (0: absent, 1: occasional, i.e., present less than 50% of the time; 2: frequent, i.e., present more than 50% of the time; 3: continuous, but interrupted by strong sensory stimuli and 4: continuous, not interrupted by strong sensory stimuli). Total
horizontal and rearing activities were then measured in the same animals in the open-field arenas (described above) for 10 min, i.e., 35 min postinjection of saline, sarizotan, \textit{l}-DOPA/benserazide alone or sarizotan+\textit{l}-DOPA/benserazide in combination.

BrdU labeling and tissue processing

To assess levels of cell proliferation by the BrdU procedure, the abovementioned rats which had been treated chronically with saline, sarizotan, \textit{l}-DOPA/benserazide, or sarizotan+\textit{l}-DOPA/benserazide in combination and studied behaviorally in terms of thigmotaxis, corner time, rotations, AIMS, and motor activity were repeatedly administered with BrdU. Individual doses of 50 mg/kg BrdU (Sigma) i.p. were given every 2 h for a total of four injections over 8 h. Rats were then sacrificed 24 h after the last BrdU injection. Rats were deeply anesthetized using a combination of ketamine (80 mg/kg; i.p.) and xylazine (10 mg/kg; i.p.) in sterile 0.9% saline and were then perfused with phosphate buffered saline (0.1 M PBS, pH 7.4) followed by perfusion with 4% paraformaldehyde (Sigma) in 0.1 M PBS. Entire brains were post-fixed in the same fixative overnight at 4°C and then cryoprotected by immersion in 30% sucrose in 0.1 M PBS at 4°C for 48 h. Brains were finally frozen and sectioned at 40 \( \mu \)m using a cryostat at −20°C (Leica CM1850, Nussloch, Germany) and stored in 0.1 M PBS at 4°C until staining.

Immunohistochemistry

For BrdU and Ki-67 immunohistochemistry, sections were permeabilized (15 min in 1% Triton X-100/0.1 M PBS), denaturated (30 mins in 2 M HCl at 37°C), and then neutralized with boric acid (10 mins at RT in 0.1 M H\textsubscript{3}BO\textsubscript{3} (pH 8.5)). Sections were blocked for 1 h in a blocking solution (3% Normal Goat Serum, 0.3% Triton X-100 in 0.1 M PBS at RT) followed by incubation overnight in primary antibody (Rat anti-BrdU, 1:500, Accurate Chemical, Westbury, NY; Rabbit anti-Ki-67, 1:1000, Novocastra, Newcastle upon Tyne, UK). Sections were then incubated 2 h at RT with an Alexa Fluor immunofluorescent secondary antibody (anti-rat IgG Alexa Fluor-488, 1:500; anti-rabbit IgG Alexa Fluor-568 1:200, Molecular Probes, Invitrogen, Sweden). Sections were finally mounted on Polylysine coated slides (Histolab, Uppsala, Sweden), dried, and coverslipped using VECTASHIELD® HardSet™ anti-fade mounting medium (Vector Laboratories). A signal amplification step was then performed by incubation in ABC reagent (ABC kit Vector Laboratories, Burlingame, CA; for 1 h) followed by a reaction with 0.05% DAB-tetrahydrochloride/0.01% hydrogen peroxide in phosphate buffer. Finally, sections were dehydrated and mounted on Polylysine coated slides (Histolab), dried, and coverslipped using VECTASHIELD® HardSet™ anti-fade mounting medium (Vector Laboratories).

Fluorescent or DAB images were captured using a Nikon digital sight DS-U1 camera using the NIS-Elements F 2.20 software.

BrdU, Ki-67, DCX, and TH quantification procedure

In these experiments, we used an established variation of design-based stereology to quantify cell proliferation (Malberg et al. 2000) to investigate sections from the entire structure in question (SVZ or SGZ). This method differs from true stereology as it is an estimation of the number of cells in the entire structure and not an actual sample of cells/volume. In brief, every eighth section throughout the hippocampus or SVZ was processed for BrdU, Ki-67, and DCX immunohistochemistry resulting in each section being 320 \( \mu \)m apart, thus ensuring that the same cell would only be counted once. The number of BrdU, Ki-67, and DCX labeled cells revealed by immunofluorescence or DAB staining was then visualized using a fluorescent microscope. Quantification in the SGZ was done using 40\( \times \) magnification by an investigator blind to treatment history who manually counted the fluorescently labeled BrdU and Ki-67 cells in the granular cell layer (GCL) and the SGZ, which is defined as a two-cell soma-wide zone along the base of the GCL. Cells were considered BrdU, Ki-67, or DCX positive when having nuclei filled with immunofluorescence or DAB and groups of clustered cells were counted as one cell. To estimate the total number of cells in the entire dentate gyrus, the number of positive cells was therefore multiplied by 8 as only every eighth section was counted. For quantification in the SVZ, an investigator blind to treatment history recorded several images at 20\( \times \) magnification along the entire SVZ for each section using image software. The images were then stitched together using Photoshop (Adobe Photoshop CS), and the resulting high definition image was then analyzed using image analysis software (Image J, NIH, Bethesda, USA). Briefly, the image was converted to an 8-bit black and white...
image which was then filtered using a preset threshold of 120. Adjoining BrdU staining cells were separated using the watershed function and finally, BrdU positive cells around or above the size of a nucleus were quantified using the analyze particles function. This image analysis method was verified using a manual counting procedure which gave comparable values. The numbers of positive cells were again multiplied by 8 to give an estimate of the total number of cells in the SVZ.

Sections which had undergone DAB staining of TH were digitized using a Dia-Scanner (Epson Perfection 4870 PHOTO). Optical density values were measured using Scion Image for Windows (alpha 4.0.3.2; © 2000–2001 Scion Corporation).

**Autoradiographic detection of DAT**

Slide mounted sections for detection of DAT were preincubated in 50 mM Tris–HCl/120 mM NaCl (pH 7.5) for 20 min. Incubation in binding buffer (50 mM Tris–HCl/120 mM NaCl, pH 7.5/1 μM fluoxetine) was conducted with 50 pM $[^{125}I]$RTI-55 (Perkin-Elmer Life Sciences, Boston, USA) for 60 min. For nonspecific binding, 100 μM nomifensine was added to the assay. The slides were washed 2 × 10 s in ice-cold binding buffer, rapidly dipped in deionized water, dried, and exposed to autoradiographic films in X-ray cassettes at −20°C for 2–7 days for $[^{125}I]$ (BioMax MR, Merck Eurolab, Sweden). The films were manually developed (Kodak D19, Unifix). Autoradiograms were digitized using a Dia-Scanner (Epson Perfection 4870 PHOTO), and optical density values were measured using Scion Image for Windows (alpha 4.0.3.2; © 2000–2001 Scion Corporation).

**Statistical analysis**

Efficacy of the unilateral 6-OHDA lesioning was analyzed using student $t$ test. AIMs were analyzed with the nonparametric Kruskal–Wallis test followed by Dunn's Multiple Comparison Test. All the other behavioral tests and immunohistochemical data on cell proliferation and neurogenesis were analyzed using two-way analysis of variance (ANOVA) followed by Bonferroni's test for pairwise comparisons.

**Results**

Efficacy of the unilateral 6-OHDA lesioning

The efficacy of the unilateral 6-OHDA lesioning in all studied rats, both from the acute and chronic experiments, was evaluated by apomorphine-induced rotations (see above). In addition, in animals from the chronic experiment, post-mortem analysis of the efficacy of the unilateral 6-OHDA lesioning was evaluated by DAB staining of TH as well as $[^{125}I]$ RTI-55 binding to DAT. As shown in Fig. 1, the 6-OHDA lesioning caused a highly significant
and near-complete reduction of TH ($t=16.36$ and $df=42$; $p<0.0001$) and DAT ($t=24.63$ and $df=22$; $p<0.0001$) at the level of striatum. There was also a significant reduction ($t=4.85$ and $df=35$; $p<0.0001$) of DAT binding at the level of hippocampus (76.96±2.874% of intact side).

Sarizotan reduced immobility in mFST of unilaterally 6-OHDA-lesioned rats

Learned-helplessness models, in which experimental animals are exposed to inescapable aversive situations, e.g., the mFST, are of utility for predicting antidepressant efficacy. During these tests, rats show alternate periods of agitation and immobility (Porsolt et al. 1977; Lucki 1997). It is well established that acute treatment with various antidepressant drugs specifically reduces immobility in these tests without nonspecific increases in motor activity. Two-way ANOVA analysis (treatment×dopamine level) showed a significant difference for treatment ($F_{[2,50]}=4.0$; $p<0.05$), but not for the dopamine level ($F_{[1,50]}=2.0$; $p>0.05$) and their interaction ($F_{[2,50]}=1.3$; $p>0.05$). Subsequent pairwise analysis showed that there was a strong trend for unilaterally 6-OHDA-lesioned rats to be more immobile in the mFST compared to normal rats ($p=0.08$). The post-hoc analysis showed that both doses of sarizotan (1 and 2.5 mg/kg, i.p.) significantly reduced immobility in unilaterally 6-OHDA-lesioned rats, but not in the normal rats (Fig. 2a). This reduction in immobility appeared to be independent of a general increase in motor activity since sarizotan had no effect on horizontal activity (treatment ($F_{[2,50]}=0.32$; $p>0.05$); dopamine level ($F_{[1,50]}=0.68$; $p>0.05$), or their interaction ($F_{[2,50]}=1.9$; $p>0.05$) neither in unilaterally 6-OHDA-lesioned nor in normal rats (Fig. 2b).

Effects of sarizotan and L-DOPA/benserazide on thigmotaxis and corner time of unilaterally 6-OHDA-lesioned rats

Thigmotaxis, i.e., peripheral activity divided by total horizontal activity and corner time are qualitative measures of motor activity thought to underlie anxiety-like behaviors. Preliminary data indicated no effect of sarizotan alone on these measures, so we decided to study effects of sarizotan alone and in combination with L-DOPA/benserazide. Two-way ANOVA analysis (treatment×day) showed significant treatment differences both on thigmotaxis (treatment ($F_{[3,33]}=10.9$; $p<0.0001$); but not on day ($F_{[3,33]}=3.4$; $p>0.05$) or their interaction ($F_{[3,33]}=0.82$; $p>0.05$)) and corner time (treatment ($F_{[3,33]}=9.4$; $p<0.0001$); but not on day ($F_{[3,33]}=2.0$; $p>0.05$) or their interaction ($F_{[3,33]}=0.03$; $p>0.05$)). As shown in Fig. 3, pairwise analyses demonstrated that chronic treatment with L-DOPA/benserazide significantly decreased thigmotaxis and corner time compared to animals treated with saline or sarizotan. Sarizotan alone had
Effects of sarizotan on L-DOPA/benserazide-induced rotations, AIMs, and motor activity in 6-OHDA-lesioned rats

To confirm that sarizotan, in our experimental setting, has beneficial actions against the development of motoric L-DOPA-induced side-effects, we examined whether it could reduce L-DOPA-induced effects on supersensitized rotations, AIMs, and motor activity. Unilaterally 6-OHDA-lesioned rats were treated with saline, sarizotan, L-DOPA/benserazide alone or sarizotan+L-DOPA/benserazide in combination for 24 days. As shown in Fig. 4a, rotational behaviors were measured on days 1 and 24, and a two-way ANOVA analysis (treatment×day) showed a significant difference for treatment ($F_{[3,38]}^{[3,38]} 14.5; p<0.0001$), but not for the day ($F_{[1,38]}^{[1,38]} 2.85; p>0.05$). A significant interaction between treatment and day was found ($F_{[3,38]}^{[3,38]} 5.59; p<0.01$). Subsequent pairwise analysis showed that sarizotan alone had no effect on rotations, while for L-DOPA/benserazide alone, the number of rotations was significantly increased on day 24. Following co-treatment with sarizotan+L-DOPA/benserazide for 24 days, there were significantly fewer rotations compared to treatment with L-DOPA/benserazide alone. To better characterize the supersensitive responsivity and possible disadvantageous effects of L-DOPA/benserazide and its reversal by sarizotan, we also measured AIMs on day 24. An overall analysis using the non-parametric Kruskal–Wallis test showed significant differences ($\chi^2 14.23; p<0.001$) between the studied groups, and in agreement with previous studies (e.g., Lundblad et al. 2004; Zhang et al. 2008), repeated L-DOPA/benserazide treatment increased AIMs when compared to saline ($p<0.01$) (Fig. 4b). Moreover, rats co-treated with sarizotan and L-DOPA/benserazide showed significantly ($p<0.05$) lower AIMs scores as compared to rats treated with L-DOPA/benserazide alone (Fig. 4b). To assess whether the effects of sarizotan on L-DOPA/benserazide-induced hyperactivity was related to a general reduction in motor activity or more specifically involved in lowering AIMs, the motor activity was measured in open-field boxes on days 1 and 24. A two-way ANOVA analysis (treatment×day) showed significant differences on horizontal activity both for treatment ($F_{[3,38]}^{[3,38]} 13.3; p<0.0001$) and day ($F_{[1,38]}^{[1,38]} 8.4; p<0.01$), but not for interaction ($F_{[3,38]}^{[3,38]} 0.84; p>0.05$). Pairwise analysis showed that chronic treatment with either L-DOPA/benserazide or combined sarizotan+L-DOPA/benserazide significantly increased horizontal activity on day 24 when compared to rats treated with saline or sarizotan alone. No difference between L-DOPA/benserazide- and sarizotan+L-DOPA/benserazide-treated rats was found (Fig. 4c). There were no significant differences between any of the studied groups on rearing activity (treatment ($F_{[3,38]}^{[3,38]} 0.39; p>0.05$); day ($F_{[1,38]}^{[1,38]} 3.6; p>0.05$) or their interaction ($F_{[3,38]}^{[3,38]} 0.26; p>0.05$) (Fig. 4d).
Sarizotan increases cell proliferation in the SVZ in a 6-OHDA-lesioned hemisphere.

To further examine whether sarizotan may have antidepressant-like properties, histological measures of cell proliferation, known to be regulated by antidepressants, were studied. Unilaterally 6-OHDA-lesioned rats were subchronically treated with saline, sarizotan, or L-DOPA/benserazide alone or sarizotan+L-DOPA/benserazide in combination for 24 days. To examine cell proliferation using the incorporation of BrdU, rats were treated with multiple BrdU injections (4×50 mg/kg every 2 h) on the 23rd day and sacrificed 24 h after the last BrdU injection. Subsequently, immunohistochemical visualization of incorporated BrdU staining cells was made in the SVZ (Fig. 5). Two-way ANOVA analysis (treatment×dopamine level) showed a significant difference for treatment ($F_{[3,34]}=5.7$; $p<0.01$), but not for the dopamine level ($F_{[1,34]}=0.38$; $p>0.05$) or their interaction ($F_{[3,34]}=0.38$; $p>0.05$). Pairwise analyses showed that treatment with sarizotan or L-DOPA/benserazide alone or sarizotan+L-DOPA/benserazide in combination significantly increased cell proliferation in the 6-OHDA-lesioned side. No significant effect of these treatments was found in the intact hemisphere.

It was unfortunately impossible to distinguish individual DCX positive cells in the SVZ as they were densely packed and no reliable quantification could be performed (data not shown).
Sarizotan increases cell proliferation and neurogenesis in the SGZ of the dentate gyrus of hippocampus in a 6-OHDA-lesioned hemisphere.

In the hippocampus, adult neurogenesis occurs in the granular zone of the dentate gyrus, beginning with cell proliferation in the SGZ. The experiment was designed to examine both cell proliferation (measured by BrdU and Ki-67) and neurogenesis (measured by DCX) in this region. In studies of BrdU incorporation, a two-way ANOVA analysis (treatment×dopamine level) showed a significant difference for treatment ($F_{3,36}$ 7.4; $p<0.01$), but not for the dopamine level ($F_{1,36}$ 1.4; $p>0.05$) or their interaction ($F_{3,36}$ 1.3; $p>0.05$). Subsequent pairwise comparisons revealed that treatment with sarizotan alone or in combination with L-DOPA/benserazide significantly increased BrdU incorporation in the 6-OHDA-lesioned side in comparison to saline as well as L-DOPA/benserazide alone (Fig. 6a, b). No significant effect of the treatments was found in the intact hemisphere.

To examine neurogenesis in the SGZ, measurements of DCX were made. Two-way ANOVA analysis (treatment×dopamine level) showed a significant differ-
ence for DCX staining for treatment ($F_{[3,36]} = 2.9; p < 0.05$), but not for the dopamine level ($F_{[1,36]} = 1.6; p > 0.05$) or their interaction ($F_{[3,36]} = 1.2; p > 0.05$). Pairwise comparisons showed that neither sarizotan nor L-DOPA/benserazide had any significant actions by themselves, but their combination increased DCX levels in the 6-OHDA-lesioned side compared to saline and L-DOPA/benserazide alone (Fig. 8a, b). No significant effect of any of the studied treatments was found in the intact hemisphere.
Discussion

The major findings of this study are that sarizotan has antidepressant-like activity in a behavioral and in a histological measure. In unilaterally 6-OHDA-lesioned rats, sarizotan significantly reduces immobility in the modified forced swim test. Moreover, sarizotan stimulates cell proliferation in both the SGZ and SVZ in the 6-OHDA-lesioned hemisphere.

One third of the patients suffering from PD exhibit clinically significant depressive symptoms which contribute to severe disability, impaired quality of life, and shortened life expectancy (Chaudhuri et al. 2006; Reijnders et al. 2008). There is a lack of established evidence-based treatments against depression in PD and a complication is that resting tremor is worsened by SSRIs in many PD patients (Chaudhuri et al. 2006). Moreover, it actually appears that the biochemical responsivity towards SSRIs differ between PD patients with co-morbid depression and patients with only depression (Pålhagen et al. 2010). It is therefore of clinical importance to find novel compounds for the treatment of depression and anxiety in PD.

In the present study, we hypothesized that sarizotan may have antidepressant properties. To address this question, we studied effects of sarizotan in the mFST, an acute test of an inescapable aversive situation, with predictive validity to assess antidepressant efficacy (Lucki 1997). Using the mFST procedure, there was a strong tendency for the 6-OHDA-lesioned rats to be more immobile ("depression-like") than normal rats. Interestingly, sarizotan significantly reduced the immobility of unilaterally 6-OHDA-lesioned rats. This antidepressant-like effect of sarizotan cannot simply be explained by a general motor activation since the same concentration of sarizotan did not have any effect on horizontal activity in the open field. Sarizotan also tended to cause an antidepressant-like action in the mFST of normal rats. To further establish antidepressant properties of sarizotan, it would be important to study its actions in additional animal paradigms for antidepressant-like efficacy, like the novelty suppressed feeding test (Santarelli et al. 2003). However, bilateral 6-OHDA-lesioned rats or other symmetric models of Parkinsonism are better suited than unilaterally 6-OHDA-lesioned rats for analysis in this test.

It is known that 5-HT1A receptors regulate anxiety-like behaviors and the partial 5-HT1A receptor agonist buspirone is clinically used as an anxiolytic agent. Based on its affinity towards 5-HT1A receptors, sarizotan could regulate anxiety-like behaviors. However, we could not find any effects of sarizotan on thigmotaxis or corner time in the open field. These data are in agreement with a previous study showing that sarizotan had no effect on marble
burying behavior in mice, another putative preclinical test for anxiety (Bruins et al. 2008). Future experiments may evaluate the effects of sarizotan in other tests of anxiety, such as the elevated plus maze and dark–light box. Somewhat surprisingly, treatment with L-DOPA/benserazide reduced thigmotaxis and corner time. This effect of L-DOPA/benserazide cannot be explained by changes in rearing activity, often reflecting stereotypies, but may be biased by L-DOPA/benserazide-induced dyskinetic and rotational behaviors making it more secure for the rat to stay in the center of the arena. In any case, to our knowledge, such effects of L-DOPA/benserazide are not well-characterized and could indicate anxiolytic properties of L-DOPA/benserazide in hemiparkinsonian rats. It should also be noted that PCP-treated rats exhibit a reduced thigmotaxis (Ericson et al. 1991), indicating that certain psychotomimetic responses may lead to reduced thigmotaxis. The functional importance underlying the reduced thigmotaxis by L-DOPA/benserazide needs to be determined in follow-up experiments. Sarizotan did not significantly counteract this action of L-DOPA/benserazide.

Our behavioral data are also in agreement with the previous studies showing that sarizotan, at 2.5 mg/kg, exhibited antidyskinetic actions without any effects on locomotor response to L-DOPA/benserazide in experimental Parkinsonian rats (Bibbiani et al. 2001; Gerlach et al. 2011). Bibbiani and co-workers suggested that this effect of sarizotan could be due to the inhibitory action of 5-HT1A autoreceptors in regulating the release of dopamine formed as a false neurotransmitter from exogenous L-DOPA in serotonin neurons. Indeed, co-treatment with a 5-HT1A receptor antagonist inhibits the antidyskinetic and sensitizing effects of sarizotan (Bibbiani et al. 2001; Gerlach et al. 2011). In addition, some specific effects of sarizotan on locomotive dyskinesia and dystonia are counteracted by D3 receptor agonism (Gerlach et al. 2011). Initial proof-of-concept trials actually demonstrated an antidyskinetic effect in patients suffering from PD (Bara-Jimenez et al. 2005), but this effect could not be replicated in a larger follow-up trial (Goetz et al. 2007). However, a subpopulation of PD patients may benefit from sarizotan treatment. Indeed, our data indicate that advanced PD patients with co-morbid depression could benefit from sarizotan to prevent the development of severe dyskinesias and counteract symptoms of depression.

To further study antidepressant-like properties of sarizotan, we performed histological studies of its effects on cell proliferation and neurogenesis. Indeed, it has been shown that chronic, but not acute, treatment with distinct antidepressants increases cell proliferation and neurogenesis in the SGZ in the dentate gyrus of the hippocampus (Malberg et al. 2000). As mentioned above, the stimulatory effects of antidepressants on cell proliferation involves activation of 5-HT1A receptors (Banasr et al. 2004; Radley and Jacobs 2002; Santarelli et al. 2003). Because of the high affinity of sarizotan at 5-HT1A receptors, the antidepressant-like

**Fig. 8** Chronic treatment with sarizotan increases neurogenesis in the SGZ of the hippocampus. a Representative images from the granular layer of the hippocampus showing differences in numbers of DCX positive cells after treatment with saline (n=4), sarizotan (n=5), or L-DOPA/benserazide (n=9) alone or sarizotan+L-DOPA/benserazide in combination (n=5) in the lesioned side. b Quantification of DCX positive cells in the granular layer revealed significant increases in neurogenesis after treatment with sarizotan+L-DOPA/benserazide in combination. *p<0.05 versus saline in the lesioned side; #p<0.05 versus L-DOPA/benserazide in the lesioned side; two-way ANOVA followed by Bonferroni’s test.
actions of sarizotan in the mFST and the lack of knowledge of serotonergic influence on cell proliferation/neurogenesis in parkinsonian models, we studied effects of sarizotan on various aspects of cell proliferation/neurogenesis in unilaterally 6-OHDA-lesioned rats. An interesting observation throughout this histological study was that sarizotan had more potent effects in the regulation of cell proliferation/neurogenesis in the 6-OHDA-lesioned hemisphere than in the intact hemisphere. Measurements of BrdU incorporation or endogenous Ki-67 staining were used to study cell proliferation and revealed that treatment with sarizotan alone or in combination with L-DOPA/benserazide increased cell proliferation in the SGZ of the hippocampus in the 6-OHDA-lesioned hemisphere. The number of BrdU positive cells was proportionately smaller to Ki-67. It is therefore likely that the injected BrdU did not label the entire population of dividing cells. However, other unknown factors may also underlie this discrepancy, especially since L-DOPA/benserazide only increased cell proliferation when measured with Ki-67. Whereas sarizotan alone had effects in both assays of cell proliferation in the SGZ, this was only manifested as a trend for an increase in neurogenesis, as measured by the immature neuronal marker DCX. This is not contradictory considering that DCX is a measure of later stages of the neurogenic process and not necessarily directly proportionate to cell proliferation. Neurogenesis was significantly increased in the SGZ by sarizotan when it was combined with L-DOPA/benserazide. Thus, overall, these data support proliferating/neurogenic effects of sarizotan in the SGZ in a 6-OHDA-lesioned hemisphere. Based on the literature and the pharmacological profile of sarizotan, it is likely that 5-HT1A receptors have a significant role in these histological actions of sarizotan in the SGZ. However, to definitively conclude that sarizotan exerts stimulatory effects on cell proliferation and neurogenesis via stimulation of 5-HT1A receptors, it would be necessary to perform experiments in which selective 5-HT1A receptors antagonists and/or 5-HT1A receptors knockout mice are used to modify the actions of sarizotan.

It was also found that sarizotan increased cell proliferation in the SVZ at the level of striatum. In agreement with previous work (e.g., Hoglinger et al. 2004), L-DOPA/benserazide also increased cell proliferation in this neurogenic niche. No additive effect of sarizotan and L-DOPA was found. Sarizotan has affinity for dopamine D2-like receptors which are present in the SVZ and appears to regulate cell proliferation in this region (Kippin et al. 2005; Newton and Duman 2007), not least in Parkinsonism (Hoglinger et al. 2004; Yang et al. 2008). D2-like receptors could be important in mediating effects of sarizotan on cell proliferation in the SVZ. Indeed, as pointed out by Bartoszyk et al. (2004), sarizotan has some intrinsic dopaminergic activity, as higher doses induce contralateral rotational behavior in unilaterally 6-OHDA-lesioned rats. Moreover, recent data (Gerlach et al. 2011) have implicated D3 receptors in mediating some antidyskinetic and antidystonic responses of sarizotan. It would be informative to study whether D3 receptor ligands and/or D3 KO mice modulate effects of sarizotan on cell proliferation, particularly in the SVZ.

In conclusion, the behavioral and neurogenic effects of sarizotan are reminiscent to the actions of several antidepressant agents (Malberg et al. 2000; Sahay and Hen 2007). These data suggest that compounds with a pharmacological profile of sarizotan could not only be useful for the treatment of L-DOPA-induced dyskinesias, but could also positively influence non-motor symptoms, such as depression and neurorestorative mechanisms in Parkinsonism.

Acknowledgements The authors declare that they have no conflict of interest. This work was supported by Parkinsonfonden, Vetenskapsrådet, Torsten and Ragnar Söderberg’s stiftelse, Hjärnfonden. We would like to thank Dr Gerd Bartoszyk, Merck KGA, for the generous gift of sarizotan.
