In-Depth Analysis of Organic Solar Cells Using Transport Equation and Optical Transfer Matrix Method with Detailed Analytical Derivations

Md. Shofiqul Islam

Department of Electrical and Computer Engineering, Faculty of Engineering, King Abdulaziz University, P.O. Box 80204, Jeddah 21589, Saudi Arabia; msislam@kau.edu.sa

Abstract: Thin-film organic solar cell (OSC) performances have been investigated in detail by improved analytical computation in this work. The generation of excitons inside OSC has been estimated by using the optical transfer matrix method (OTMM) to include the optical phenomena of the incident light. The dissociation of these excitons into free charge carriers has been investigated to find the most appropriate one. OSC performances have been evaluated by an improved analytical solution of electrical transport equations including (i) exciton generation obtained from OTMM, (ii) dissociation probability incorporating Gaussian distribution to account for the natural fact of the difference in photon-energy producing excitons, (iii) recombination of charge carriers, all together. OSC properties such as $J_{SC}$, $V_{OC}$, FF, PCE, $P_{max}$, absorbance, and quantum efficiency have been investigated with the variation of different parameters; this might be useful to improve OSC. Again, the presented detailed derivations of analytical expressions would be helpful for clear understanding.

Keywords: properties of organic solar cell; analytical computation; electric transport equation; optical transfer matrix method; detailed analytical derivations; appropriate dissociation probability

1. Introduction

An organic solar cell (OSC) looks like a good candidate for harvesting solar energy because it has some advantageous features compared to its counterpart conventional Si solar cells [1–3]. OSCs are basically made of layers of different materials; one layer is photoactive which consists of two organic materials such that one organic material (usually conjugated polymer) has the property to donate electrons and another organic material (usually fullerene) has the property to accept electrons, i.e., donor and acceptor. Due to light absorption in the photoactive layer, excitons (firmly bounded electron-hole-pairs) are generated. Then these excitons are dissociated into free charge carriers (electrons and holes). Dissociation occurs when excitons interact with donor-acceptor interfaces, defects, etc.; donor-acceptor interface has an internal electric field like a pn junction diode; therefore, this interface is the most effective site for dissociation. A bi-layered OSC has only one donor-acceptor interface; only the excitons, generated very near to this single interface, can reach the interface and be dissociated. However, for bulk hetero-junction (BHJ) OSC, the active layer is made of a mixer of donor and acceptor materials, lots of donor-acceptor interfaces, hence almost all generated excitons can get nearby interface and can be dissociated. As a result, BHJ OSC is more efficient than bi-layered OSC; therefore, many people [4–6] are working with BHJ OSC for its improvement. Some researchers [7] reported BHJ OSC with the internal quantum efficiency of 100%; but the useful external efficiency is only 10%.
For the further improvement of BHJ OSC, works regarding the structure and/or layer materials are required. The theoretical analysis (physics-based/simulation) can help in this regard. Some theoretical works have been done by numerical methods [8–11] and some other works have been done with analytical calculations [12–14].

Although few numerical methods are robust regarding initial guesses, for most of the numerical methods it is observed that they are complicated and highly dependent on an initial guess, whereas, analytical calculation provides more correct results directly without the need for an initial guess. In this work, BHJ OSC will be investigated using analytical calculations. The accuracy of the analytical result depends on the way of treating the generation of excitons, dissociation of excitons into charge carriers, and recombination of charge carriers.

Regarding the use of generation rate in analytical calculations, some researchers [12] utilized empirical fitting quantities; some other group [14] used constant generation rate for making analytical calculations easier. However, for a thin layered device like OSC, constant generation rate approximation is not suitable, because due to thin layer, the incident light will not be reduced to zero while passing a layer, and hence it will be reflected and refracted at the interface with next layer, then there will be interference between incident-light and reflected-light, hence, the resultant light intensity will be different at different positions. As a result, the excitons will be different at different positions, i.e., excitons will be position dependent. Many researchers used exciton generation rate exponentially decreasing with position (Beer–Lambert law), but this neglects the impacts of optical phenomena (refraction, reflection, and interference). However, for the thin layered device, the effects of optical phenomena cannot be ignored, hence exponentially decreasing generation rate model would not be suitable also. Again, depending on the bandgap size of active layer material, photons with some wavelengths will be absorbed effectively, some other wavelengths will not be so effective, that is, the exciton generation will also depend on wavelength. The Optical Transfer Matrix Method (OTMM) considers the effects of optical phenomena and wavelength-dependent properties of layer materials, hence OTMM provides the generation rate as the function of both position and wavelength [3,11,15,16]. Therefore, the OTMM-based generation rate is most suitable for thin layered OSC and hence it has been used in this work for a more accurate result.

Regarding recombination, we see that many analytical works [14,17–19] neglected recombination; but recombination is a vital factor as it affects current and other performances [20]. Some analytical works considered recombination, but they used generation rate either constant [21] or exponentially decreasing [22]; however, as stated earlier, the constant or exponential model is not as accurate as the OTMM-based generation rate for the thin layered device. Some other works [18,19] used OTMM based generation rate but neglected recombination.

Another factor is the dissociation rate function used for calculating dissociation probability for computing charge carriers from the excitons. Based on Onsager’s theory [23], Braun introduced the dissociation rate function [24]. Previous researchers [8,11] used the Braun model, and recently, people [21,25] are using the Wojcik and Tachiya model which is an improved version of the Braun model. Both models used constant (same) separation distance between electron and hole for all excitons. However, naturally, for any device, the electron-hole-separation distances will be different for different excitons because of the difference in photon-energy producing excitons. To address this fact, a standard distribution function may be applied along with Braun or Wojcik model.

To the best of my knowledge, in literature, no analytical work on OSC considered (i) OTMM-based exciton, (ii) dissociation probability including standard distribution function, (iii) recombination of charge carriers, all together. While including all these three factors together, the analytical solution becomes complicated, however, it is assumed necessary to get a better result. Again, most of the reported works usually calculate J–V, P–V, efficiency for a fixed condition; there are few works on the investigation with the variety
of different factors, especially, no investigation work used above factors altogether. Moreover, almost all reported analytical works presented the final form of analytical expressions, no details about the derivation, in that case, it does not become clear about the limitations or assumptions used in the derivation.

To fill the aforementioned deficits in literature, this work has been done with the following targets. Target 1: Improved analytical calculations of OSC performances including the following three factors all together: (i) exciton generation rate obtained from OTMM to include optical phenomena, (ii) dissociation probability obtained by incorporating Gaussian distribution to consider the natural fact of the difference in electron-hole-separation distances, (iii) recombination of charge carriers. Target 2: Analysis of different OSC properties in detail with the variation of terminal voltage, irradiance, wavelength, active layer thickness using the above-mentioned improved analytical calculation. Target 3: The detailed derivations of analytical expressions with a view to making the work clear regarding limitations and assumptions and easy understanding for the OSC researchers, especially, for the new ones.

2. Excitons

When light falls on thin-layered OSC, excitons are generated by photons inside the photo-active layer (organic material). The distribution of light (hence the distribution of excitons) inside the active layer may be obtained by using the Optical Transfer Matrix Method (OTMM). Many works used OTMM-based equations. However, detailed derivation of OTMM-based equations is being presented here for better understanding.

Let us consider m layer (thin) device sandwiched between air and substrate (thick) as shown in Figure 1. The air is designated as 0th layer and the substrate as (m + 1)th layer.

According to OTMM, while light crosses the interface of layer 0 and layer 1, the refraction and reflection behavior of light may be expressed by an interface matrix \( I_{01} \), for perpendicular light falling, as follows [11].

\[
I_{01} = \begin{bmatrix}
\frac{(\tilde{n}_0 + \tilde{n}_1)}{2\tilde{n}_0} & \frac{(\tilde{n}_0 - \tilde{n}_1)}{2\tilde{n}_0} \\
\frac{(\tilde{n}_0 - \tilde{n}_1)}{2\tilde{n}_0} & \frac{(\tilde{n}_0 + \tilde{n}_1)}{2\tilde{n}_0}
\end{bmatrix}
\]  

(1)

where, \( \tilde{n}_0 \) and \( \tilde{n}_1 \) are complex refractive indices of layer 0 and layer 1.

Again, according to OTMM, while light passes through layer 1, the absorption behavior of light may be expressed by a layered matrix \( L_1 \), for perpendicular light falling, as follows [11].
\[
L_1 = \begin{bmatrix}
\exp(-i\xi_1d_1) & 0 \\
0 & \exp(i\xi_1d_1)
\end{bmatrix}
\] (2)

where, \(\xi_1 = (2\pi\eta_1/\lambda)\); \(d_1\) = thickness of layer 1; \(\xi_1d_1\) = change of phase angle as the light passes through the layer 1.

Similarly, calculating all interface matrices and layer matrices, for the whole structure, a scattering matrix (transfer matrix) \(S\) may be formed as follows.

\[
S = L_0L_1L_2 \ldots \ldots L_{(m-1)}mL_m(m+1)
\] (3)

At any position inside the device, the optical electric field (E) has two components: \(E^+\) (forward component along positive \(x\)) and \(E^-\) (backward component along negative \(x\)) as shown in Figure 1.

The components of \(E\) inside 0th layer may be related to those inside \((m+1)\)th layer via the \(S\) matrix as follows.

\[
\begin{bmatrix}
E_0^+ \\
E_0^-
\end{bmatrix} = S
\begin{bmatrix}
E_{m+1}^+ \\
E_{m+1}^-
\end{bmatrix}
\] (4)

As the substrate is thick, no reflected light inside substrate, i.e., \(E_{m+1}^- = 0\). Using \(E_{m+1}^- = 0\) in the above equation, we may get, \(E_0^+ = S_{11}E_{m+1}^+\) and \(E_0^- = S_{21}E_{m+1}^+\). Now for whole system, we may get reflection coefficient, \(r = E_0^- / E_0^+ = S_{21}/S_{11}\) and transmission coefficients, \(t = E_{m+1}^+ / E_0^+ = 1/S_{11}\).

To determine the distribution of light (hence distribution of excitons) inside the active layer (\(j\)th layer), we need to treat the active layer matrix \((L_j)\) separately. Therefore, the \(S\) matrix may be divided into three segments such that \(S = S'L_jS''\).

\[
S' = \text{Sub matrix before } L_j = L_0L_1L_2 \ldots \ldots L_{(j-1)}L_{(j-1)}j
\]

\[
S'' = \text{Sub matrix after } L_j = L_{(j+1)}L_{(j+1)} \ldots \ldots L_mL_m(m+1)
\] (5) (6)

Like the whole system \((S)\), reflection and transmission coefficients for subsystems \((S'\) and \(S'')\) may be defined as \(r' = S_{21}'/S_{11}'\); \(t' = 1/S_{11}'\); \(r'' = S_{21}''/S_{11}''\); \(t'' = 1/S_{11}''\).

Assuming the left edge of the \(j\)th layer is \(x = 0\), the optical electric field \(E_j(x)\) at a position \(x\) inside the \(j\)th layer can be written as

\[
E_j(x) = E_j^+(x) + E_j^-(x)
\] (7)

If we assume \(E_j^+\) and \(E_j^-\) as the forward and backward field components at the beginning of \(j\)th layer (Figure 1), then we get Equation (8) (see Appendix A).

\[
E_j(x) = E_j^+ x + E_j^- x\exp(-i\xi_jx)
\] (8)

If we define an internal forward transfer coefficient \((t_j^+\) as \(t_j^+ = E_{j+1}^+/E_j^+\) then we get Equation (9) (see Appendix B).

\[
E_j(x) = t_j^+E_j^+ x r'' x\exp(i\xi_j(2d_j - x))
\] (9)

The value of \(t_j^+\) may be found by the Equation (10) (see Appendix C).

\[
t_j^+ = E_{j+1}^+/E_j^+ = [S_{11}'' + S_{12}'' \exp(i\xi_jd_j)]^{-1}
\] (10)
As \( r'' (= S''_{11}/S''_{11}) \) is a complex term, it can be expressed in polar form as \( r'' = \rho'' \exp(i\delta'') \) where \( \rho'' \) and \( \delta'' \) are the magnitude and angle of \( r'' \). By putting \( r'' = \rho'' \exp(i\delta'') \) and \( \xi_j = 2\pi\tilde{\eta}_j/\lambda \) in Equation (9), we get

\[
E_j(x) = t_j^+ E_0^+ \left[ \exp\left( i2\pi\tilde{\eta}_j x/\lambda \right) + \rho'' \exp(i\delta'') \exp\left( i2\pi\tilde{\eta}_j (2d_j - x)/\lambda \right) \right] \tag{11}
\]

Putting \( \tilde{\eta}_j = \eta_j + i\kappa_j \) in Equation (11) and algebraic manipulation gives the Equation (12) (see Appendix D).

\[
|E_j(x)|^2 = |t_j^+|^2 |E_0^+|^2 \left[ \exp(-\alpha_j x) + L \exp(\alpha_j x) + M \cos(N - Rx) \right] \tag{12}
\]

where, \( \alpha_j = 4\pi\kappa_j/\lambda; L = \rho''^2 \exp(-2\alpha_j d_j); M = 2\rho'' \exp(-\alpha_j d_j); N = (4\pi\tilde{\eta}_j d_j/\lambda + \delta''); R = 4\pi\tilde{\eta}_j/\lambda. \)

Note that, \( \alpha_j \) is the absorption coefficient (unit: m\(^{-1}\)).

Assigning, \( H(x) = [\exp(-\alpha_j x) + L \exp(\alpha_j x) + M \cos(N - Rx)] \) we may write Equation (12) as

\[
|E_j(x)|^2 = |t_j^+|^2 |E_0^+|^2 H(x) \tag{13}
\]

Irradiance \( I \) may be expressed as, \( I = (1/2)ceE^2 \), where \( c \) = light speed, \( \varepsilon = \varepsilon_{vac} \varepsilon_r \) = electric permittivity, \( \varepsilon_{vac} \) = vacuum permittivity, \( \varepsilon_r \) = relative permittivity or dielectric constant, \( E \) = electric field (see Appendix E).

Accordingly, the irradiance at position \( x \) in \( j^{th} \) layer is,

\[
I_j(x) = (1/2)c\varepsilon|E_j(x)|^2 = (1/2)c\varepsilon |t_j^+|^2 |E_0^+|^2 H(x) \tag{14}
\]

Using the relation between refractive index and electric permittivity, \( I_j(x) \) may be expressed by Equation (15) (see Appendix F).

\[
I_j(x) = \left( \eta_j/\eta_0 \right) |t_j^+|^2 I_0 H(x) \tag{15}
\]

If the irradiance \( I_j(x) \) (unit: Wm\(^{-2}\) or Js\(^{-1}\)m\(^{-3}\)) is multiplied with absorption coefficient \( \alpha_j \) (unit: m\(^{-1}\)), it will give the power dissipated per unit volume as \( Q_j(x) = \alpha_j I_j(x) \) (unit: Js\(^{-1}\)m\(^{-3}\)). We know, photon energy \( = h\nu = (hc/\lambda) \) (unit: J); where \( h \) = Planck’s constant. If we divide \( Q_j(x) \) by photon energy, we will obtain absorbed photon rate per unit volume \( \left( A_{P_{\text{vol}}} \right) \) (unit: s\(^{-1}\)m\(^{-3}\)) as

\[
A_{P_{\text{vol}}} = K_1 H(x) \tag{16}
\]

\[
K_1 = (\lambda/hc)\alpha_j (\eta_j/\eta_0) |t_j^+|^2 I_0 \tag{17}
\]

Like many other researchers [11], it may be assumed that each photon produces one exciton in P3HT: PCBM based OSC. Therefore, the exciton generation rate per unit volume, \( G_{\text{exc}} \) (unit: s\(^{-1}\)m\(^{-3}\)) would be equal to \( A_{P_{\text{vol}}}. \)

\[
G_{\text{exc}}(x) = K_1 H(x) \tag{18}
\]

3. Charge Carriers

Excitons are dissociated into free charge carriers (electrons and holes). To calculate these free charge carriers, we need to use dissociation probability. Geminate recombination theory of Onsager [23,26,27] may be employed to calculate dissociation probability.
Braun [24] tried to correct Onsager’s theory using a model as follows: any exciton may decay to ground state (recombine) or dissociate into free charge carriers; if the decay rate is $k_f$ and the dissociation rate is $k_{diss}$ then dissociation probability ($P$) is,

$$P = \frac{k_{diss}(r_0)}{k_{diss}(r_0) + k_f(r_0)} \quad (19)$$

The decay rate ($k_f$) is inversely proportional to separation distance ($r_0$) between electron and hole of an exciton, that is, $k_f = S_e/r_0$, where $S_e$ is the reactivity parameter (unit: ms⁻¹). The electric field ($F$) plays the main role in dissociation, that is, $k_{diss} = f(F)$. Using the work of Onsager [28], Braun introduced a formula of $k_{diss}$ including the effect of $F$ as follows.

$$k_{diss,Braun}(r_0) = \frac{3\gamma}{4\pi r_0^3} \exp \left( \frac{-U_b}{k_B T} \right) J_1(2\sqrt{-2b}) \quad (20)$$

$$J_1(2\sqrt{-2b}) \left( 1 + \frac{b^2}{3} + \frac{b^3}{18} + \cdots \right) \quad (21)$$

Here, $\gamma = q(\mu_n + \mu_p)/\epsilon = \text{recombination rate constant}; q = \text{electronic charge value}; \mu_n(\mu_p) = \text{electron (hole) mobility (unit: m²V⁻¹s⁻¹)}; U_b = q^2/(4\pi r_0) = \text{binding energy of electron-hole-pair of an exciton}; k_B = \text{Boltzmann’s constant}; T = \text{temperature in Kelvin}; J_1 = \text{first-order Bessel function of the first kind}; b = q^3|F|/(8\pi \epsilon k_B T^2) = \text{field parameter}; F = \text{electric field (unit: Vm⁻¹)}.

Many researchers [8,11,29,30] used Braun’s formula of $k_{diss}$ to calculate dissociation probability. However, for better results, Wojcik et al. [21,26] proposed a modified formula of $k_{diss}$ as given below.

$$k_{diss,Wojcik}(r_0) = \frac{D r_c}{r_0^3} \exp \left( \frac{-r_c}{r_0} \right) J_1(2\sqrt{-2b}) \quad (22)$$

where, $D = D_n + D_p$; $D_n = k_B T \mu_n/q = \text{electron diffusion coefficient (unit: m²s⁻¹)}; D_p = k_B T \mu_p/q = \text{hole diffusion coefficient}; r_c = q^2/(4\pi \epsilon k_B T) = \text{Onsager radius}$.

Braun or Wojcik formula used constant value for separation distance [21,24–26]. However, separation distances ($r$) are different, therefore, the probability ($P$) may be calculated by Equation (23) (see Appendix G).

$$P = \int_0^{\infty} \frac{k_{diss}(r)}{k_{diss}(r) + k_f(r)} f(r) dr \quad (23)$$

where, $f(r)$ is spherically averaged Gaussian distribution (SAGD) function given by

$$f(r) = \frac{4}{\sqrt{\pi r_0^3}} r^2 \exp(-r^2/r_0^2) \quad (24)$$

where, $r_0 = \text{separation distance corresponding to peak of SAGD function}$.

Note that, $\int_0^{\infty} f(r) \, dr = 1$.

After getting $P$, charge carrier generation rate, $G$ (unit: s⁻¹m⁻³) can be found as

$$G(x) = P G_{exc}(x) = KH(x) \quad (25)$$

where $K = PK_1$. 
4. Device Structure

The organic solar cell (OSC) analyzed in this work is a layered device as shown in Figure 2a. The energy levels of layer materials, shown in Figure 2b, are taken from previous works [3,7,11,31–35]. Usually, the energy band diagram shows the electron energy, therefore, all energy levels are shown with a negative sign (negative charge energy).

Naturally, low energy states are easily filled with electrons and higher energy states remain vacant. The conduction band is the lowest energy level(s) among the vacant states and the valence band is the highest energy level(s) among the filled states. Semiconductor behaviors are explained with a conduction band and valence band separated by an energy gap. Similarly, organic materials (P3HT, PCBM) behavior may be explained with LUMO (lowest unoccupied molecular orbital) and HOMO (highest occupied molecular orbital) separated by an energy gap. The mixer of P3HT and PCBM is the active layer where photons are absorbed. Active layer may be thought of as a single meta-material considering PCBM_LUMO like conduction band and P3HT_HOMO like valence band [9,10,12,14]; bandgap = (PCBM_LUMO–P3HT_HOMO) = 1 eV.

After absorbing photons, excitons are generated; for some excitons, electrons and holes are recombined; for other excitons, electrons and holes are separated and become free. Then free electrons move from P3HT_LUMO to PCBM_LUMO and free holes move from PCBM_HOMO to P3HT_HOMO shown in Figure 2(b). P3HT is (electron) donor and PCBM is (electron) acceptor. Even after movement, electrons at PCBM_LUMO and holes at P3HT_HOMO form “geminate pairs”. Afterward, these pairs are broken by the electric field and thus electrons and holes become finally free to move.

Then, finally free electrons flow from PCBM_LUMO to Al and free holes flow from P3HT_HOMO to ITO via PEDOT: PSS, as in Figure 2b. Electron-flow from P3HT to PCBM produces a current in the direction of PCBM to P3HT; hole-flow from PCBM to P3HT produces a current in the direction of PCBM to P3HT, that is, both flows produce current in the direction of PCBM to P3HT inside the device. We know, for a pn junction solar cell, the current is in the direction of n-Si to p-Si; therefore, it may be deduced that P3HT is like p-Si and PCBM is like n-Si.

As there is a current in the direction of PCBM to P3HT without the application of any external voltage, we may perceive an internal electric field inside the active layer in the direction of PCBM to P3HT (same direction of current) that causes the flow of photo-generated electrons and holes and produces the current. Both current and internal fields (PCBM to P3HT direction) are negative because conventionally the direction of P3HT to PCBM is considered positive. Corresponding to this internal field, we may perceive an internal built-in potential \( V_{bi} \) as shown in Figure 2b. This \( V_{bi} \) may be determined by the difference of energy levels of Al and PEDOT: PSS [12,14,31] which are adjacent to both sides of the active layer.

When a battery is connected to this OSC for charging, the current will come out at ITO and will charge the battery, therefore, the battery terminal which is connected to ITO will have positive polarity. Now, the battery voltage will work as the externally applied voltage (say \( V_a \)) with battery-positive at ITO (i.e., P3HT side or p-side) and battery-negative at Al (i.e., PCBM side or n-side), that is, \( V_a \) will work for forward biasing the device. This \( V_a \) will provide an electric field in the direction of P3HT to PCBM; this field is positive. Therefore, the resultant electric field inside the active layer would be \( F = (V_a - V_{bi})/d_f \), where \( d_f \) = active layer thickness.

While the electrons and holes move, some of them may be lost due to recombination within the active layer. Recombination has been considered in this work.

Here, a glass-layer has been used for the mechanical support and protection for thin layers of materials. PEDOT: PSS has been used to guide and collect holes effectively by making small energy step favorable for holes to move.
5. OSC Performances

Due to recombination and other interactions inside the device, all the generated charge carriers would not be useful for producing current. The electron current density due to current-producing electron \( n \) can be expressed as follows [36].

\[
J_n = q\mu_n n F + qD_n \frac{dn}{dx}
\]  

(26)

Note that, here \( n \) is electron density per unit volume (unit: \( \text{m}^{-3} \)), not the electron rate. The continuity equation for electrons at a steady-state would be as follows [36].

\[
- \frac{1}{q} \frac{df_n}{dx} = (G - R_n)
\]  

(27)
where, \( G \) = charge carrier (electron) generation rate (unit: \( \text{s}^{-1}\text{m}^{-3} \)), \( R_n \) = electron recombination rate = \( r_m n \), where, \( r_m \) is the monomolecular recombination coefficient (unit: \( \text{s}^{-1} \)).

In this work, \( F \) has been assumed constant like other works [10,12–14] and monomolecular recombination has been used to obtain a complete analytical solution (see Appendix H).

Using Equation (26) and Equation (27) we may obtain as

\[
\frac{d^2n}{dx^2} + a_1 \frac{dn}{dx} + a_2n = a_3G
\]

where, \( a_1 = \frac{F \mu_n}{D_n}, a_2 = -\frac{r_m}{D_n}, a_3 = -\frac{1}{D_n} \)

For the electrons due to environment temperature (dark condition), \( G = 0 \); the differential equation is

\[
\frac{d^2n}{dx^2} + a_1 \frac{dn}{dx} + a_2n = 0
\]

The solution of the differential Equation (29) is

\[
n_{dark} = A_1 \exp(\omega_{a1}x) + A_2 \exp(\omega_{a2}x)
\]

where, \( \omega_{a1} = -a_1 + \sqrt{a_1^2 - 4a_2}, \omega_{a2} = -a_1 - \sqrt{a_1^2 - 4a_2} \)

For the electrons due to photons, \( G \neq 0 \); the differential equation is

\[
\frac{d^2n}{dx^2} + a_1 \frac{dn}{dx} + a_2n = a_3G
\]

The complementary solution of the differential Equation (31) is

\[
n_{ph1} = A_3 \exp(\omega_{a1}x) + A_4 \exp(\omega_{a2}x)
\]

where “ph” stands for photon and it represents a photo-excited part.

The particular solution of the differential Equation (31) can be expressed by Equation (33) (see Appendix I).

\[
n_{ph2} = a_3K\left[a_4 \exp(-a_1x) + a_5 \exp(a_1x) + a_6 \cos(N - Rx) + a_7 \sin(N - Rx)\right]
\]

where, \( a_4 = \frac{1}{(a_1^2 - a_1a_j + a_2)}, a_5 = \frac{L}{(a_1^2 + a_1a_j + a_2)}, a_6 = \frac{M(a_2 - R^2)}{(a_2 - R^2)^2 + a_1^2R^2}, a_7 = \frac{-Ma_4R}{(a_2 - R^2)^2 + a_1^2R^2} \)

Electron due to the light for a single wavelength, \( n_{ph} \) would be the summation of \( n_{ph1} \) and \( n_{ph2} \).

\[
n_{ph} = A_3 \exp(\omega_{a1}x) + A_4 \exp(\omega_{a2}x) + a_3K\left[a_4 \exp(-a_1x) + a_5 \exp(a_1x) + a_6 \cos(N - Rx) + a_7 \sin(N - Rx)\right]
\]

Total electron (\( n \)) may be expressed as

\[
n = n_{dark} + \int_{\lambda_1}^{\lambda_2} n_{ph} d\lambda
\]

Using the boundary values of electron concentration at \( x = 0 \) and \( x = d_j \) in Equation (35), we will obtain the values of \( A_1, A_2, A_3, A_4 \) [see Appendix J].
\[A_1 = N_e \exp(-\phi_2/V_T + \omega_{a_2}d_j) - \exp(-\phi_1/V_T) / A\]  
\[A_2 = N_e \exp(-\phi_1/V_T) - \exp(-\phi_2/V_T + \omega_{a_1}d_j) / A\]  
\[A_3 = [a_g \exp(\omega_{a_3}d_j) - a_4] / A\]  
\[A_4 = [a_5 - a_g \exp(\omega_{a_1}d_j)] / A\]  

\[N_e = \text{Effective density of states at PCBM LUMO}\]  
\[\phi_2 = \text{Electron injection barrier potential at } x = 0, \text{ see Figure 2b}\]  
\[\phi_1 = \text{Electron injection barrier potential at } x = d_j, \text{ see Figure 2b}\]  
\[V_T = k_b T / q = \text{Thermal voltage}\]  

\[A = \left[ \exp(\omega_{a_2}d_j) - \exp(\omega_{a_1}d_j) \right] \]  
\[a_g = -a_3 [a_4 + a_5 + a_6 \cos(N) + a_7 \sin(N)] \]  
\[a_4 = -a_3 K [a_4 \exp(-\alpha_d j) + a_g \exp(\alpha_d j) + a_6 \cos(N - R_d) + a_7 \sin(N - R_d)] \]

By putting \( n_{\text{dark}} \) from Equation (30) into Equation (26), we may obtain electron dark current as

\[I_{\text{nph}} = A_{21} \exp(\omega_{a_1}x) + A_{22} \exp(\omega_{a_2}x) + A_{23} \exp(-\alpha_d x) + A_{24} \exp(\alpha_d x) + A_{25} \cos(N - R) + A_{26} \sin(N - R) \]  

where, \( A_{21} = (\mu_n F A_1 + q D_n A_1 \omega_{a_1}), A_{22} = (\mu_n F A_2 + q D_n A_2 \omega_{a_2}) \),

\[A_{23} = (\mu_n F a_3 K a_4 + q D_n a_3 K a_4 a_j), A_{24} = (\mu_n F a_3 K a_5 + q D_n a_3 K a_5 a_j), A_{25} = (\mu_n F a_3 K a_6 - q D_n a_3 K a_7 R), A_{26} = (\mu_n F a_3 K a_7 + q D_n a_3 K a_6 R) \]

Total electron current may be expressed as

\[I_{\text{total}} = I_{\text{nph}} + \int_{\lambda_1}^{\lambda_2} I_{\text{nph}} d\lambda \]  

Similarly, for the case of holes (p), the differential equation would be

\[\frac{d^2 p}{dx^2} + b_1 \frac{dp}{dx} + b_2 p = b_3 G \]  

where, \( b_1 = -F_{\mu_p} / D_p, b_2 = -r_m / D_p, b_3 = -1 / D_p \)

Similar solutions for holes are as follows

\[p_{\text{dark}} = B_1 \exp(\omega_{b_1}x) + B_2 \exp(\omega_{b_2}x) \]

where, \( \omega_{b_1} = -b_1 + \sqrt{b_1^2 - 4b_2} / 2, \omega_{b_2} = -b_1 - \sqrt{b_1^2 - 4b_2} / 2 \)

\[p_{\text{ph}} = B_3 \exp(\omega_{b_1}x) + B_4 \exp(\omega_{b_2}x) + b_5 K \left[ b_6 \exp(-\alpha_d x) + b_7 \exp(\alpha_d x) + b_8 \cos(N - R) + b_9 \sin(N - R) \right] \]
where, \( b_4 = \frac{1}{(\alpha_j^2 - b_1 \alpha_j + b_2)} \), \( b_5 = \frac{L}{(\alpha_j^2 + b_1 \alpha_j + b_2)} \), \( b_6 = \frac{M(b_2 - R^2)}{(b_2 - R^2)^2 + b_1^2 R^2} \), \( b_7 = \frac{-M b_1 R}{(b_2 - R^2)^2 + b_1^2 R^2} \)

Total hole, \( p = p_{dark} + \int_{\lambda_1}^{\lambda_2} p_{ph} d\lambda \) (49)

Using the boundary values of hole concentration at \( x = 0 \) and \( x = d_j \) in Equation (49) we will obtain the values of \( B_1, B_2, B_3, B_4 \)

\[
B_1 = N_v \left[ \exp(-\phi_3/V_T + \omega_{b2} d_j) - \exp(-\phi_4/V_T) \right] / B
\]

\[
B_2 = N_v \left[ \exp(-\phi_4/V_T) - \exp(-\phi_3/V_T + \omega_{b1} d_j) \right] / B
\]

\[
B_3 = [b_9 \exp(\omega_{b2} d_j) - b_8] / B
\]

\[
B_4 = [b_9 - b_8 \exp(\omega_{b1} d_j)] / B
\]

\( N_v \) = Effective density of states at P3HT HOMO
\( \phi_3 \) = Hole injection barrier potential at \( x = 0 \), see Figure 2b
\( \phi_4 \) = Hole injection barrier potential at \( x = d_j \), see Figure 2b

\[
B = \left[ \exp(\omega_{b2} d_j) - \exp(\omega_{b1} d_j) \right] \\

b_9 = -b_2 K [b_4 + b_5 + b_6 \cos(N) + b_7 \sin(N)]
\]

\[
b_9 = -b_3 K [b_4 \exp(-\alpha_j d_j) + b_9 \exp(\alpha_j d_j) + b_6 \cos(N - R d_j) + b_7 \sin(N - R d_j)]
\]

Now the hole current.

\[
J_{pdark} = B_{11} \exp(\omega_{b1} x) + B_{12} \exp(\omega_{b2} x)
\]

where, \( B_{11} = (\alpha \mu_p B_1 - \mu_p B_{12}) \), \( B_{12} = (\mu_p B_{12} - \mu_p B_{11}) \)

\[
J_{pph} = B_{21} \exp(\omega_{b1} x) + B_{22} \exp(\omega_{b2} x) + B_{23} \exp(-\alpha_j x) + B_{24} \exp(\alpha_j x) + B_{25} \cos(N - R x) + B_{26} \sin(N - R x)
\]

where, \( B_{21} = (\alpha \mu_p B_3 - \mu_p B_{24} \omega_{b1}) \), \( B_{22} = (\alpha \mu_p B_4 - \mu_p B_{25} \omega_{b1}) \), \( B_{23} = (\alpha \mu_p B_{24} B_3 - \mu_p B_{25} B_4 \alpha_j) \), \( B_{24} = (\alpha \mu_p B_{25} B_3 - \mu_p B_{26} B_4 \alpha_j) \), \( B_{25} = (\alpha \mu_p B_{24} B_3 \omega_{b1} + \mu_p B_{25} B_4 \omega_{b2}) \), \( B_{26} = (\alpha \mu_p B_{25} B_3 \omega_{b2} - \mu_p B_{26} B_4 \omega_{b2}) \)

\[
J_{ptot} = J_{pdark} + \int_{\lambda_1}^{\lambda_2} J_{pph} d\lambda
\]

Total current due to electron and hole is

\[
J_{tot} = J_{ntot} + J_{ptot}
\]

It is obvious that electron and hole currents are the functions of position (\( x \)); therefore, total current (\( J_{tot} \)) will also be the function of position. However, the total current should be position independent. By taking the average, the position-independent total current (\( J \)) may be obtained as follows [37,38].

\[
J = \frac{1}{d_j} \int_0^{d_j} J_{tot} dx
\]

The J-V characteristic can be analytically calculated by using Equation (61). Similarly, the other external properties such as the open-circuit voltage (\( V_{OC} \)), short circuit current
(Jsc), maximum power (P_{max}), fill factor (FF), power conversion efficiency (PCE) can be analytically calculated.

Again, the internal properties such as absorbance, external quantum efficiency (EQE), internal quantum efficiency (IQE) of OSC can be analytically evaluated as follows.

Absorbance is the ratio of the number of absorbed photons to the number of incident photons. Absorbance can be analytically expressed by the Equation (62) (see Appendix K)

\[
\text{Absorbance} = \frac{(\eta_j/\eta_0)t_j^2}{R} [-R\{\exp(-\alpha_j d_j) - 1\} + RL\{\exp(\alpha_j d_j) - 1\} - \alpha_j M\{\sin(N - Rd_j) - \sin(N)\}] 
\] (62)

Quantum efficiency indicates the effectiveness of the device to convert optical energy to electrical energy. External quantum efficiency (EQE) is the ratio of the number of photocurrent-producing charge carriers to the number of incident photons. Average photocurrent (J_{ph,avg}) and hence EQE can be determined as follows (see Appendix L)

\[
J_{ph,avg} = \frac{1}{d_j} \left[ \frac{A_{21}}{\omega_{a_2}} \{\exp(\omega_{a_2} d_j) - 1\} + \frac{A_{22}}{\omega_{a_3}} \{\exp(\omega_{a_3} d_j) - 1\} + \frac{B_{21}}{\omega_{b_1}} \{\exp(\omega_{b_1} d_j) - 1\} + \frac{B_{22}}{\omega_{b_2}} \{\exp(\omega_{b_2} d_j) - 1\} \right]
\]

\[
+ \frac{A_{23} + B_{23}}{-\alpha_j} \{\exp(-\alpha_j d_j) - 1\} + \frac{A_{24} + B_{24}}{-\alpha_j} \{\exp(\alpha_j d_j) - 1\} + \frac{A_{25} + B_{25}}{-R \{\sin(N - Rd_j) - \sin(N)\}} \]

\[
\text{EQE} = \frac{\text{photocurrent carrier}}{\text{incident photon}} = \frac{\left| J_{ph,avg} \right|}{I_0 / hc} = \frac{hc}{I_0 \lambda q} |J_{ph,avg}| 
\] (64)

Internal quantum efficiency (IQE) is the ratio of the number of photocurrent-producing charge carriers to the number of absorbed photons.

\[
\text{IQE} = \frac{\text{photocurrent carrier}}{\text{absorbed photon}} = \frac{\text{photocurrent carrier}}{\text{incident photon}} \times \frac{\text{incident photon}}{\text{absorbed photon}} = \frac{\text{EQE}}{\text{Absorbance}} = \frac{\text{EQE}}{1 - \text{Reflectance}} 
\] (65)

As absorbance is less than unity, IQE would be always larger than EQE.

6. Results and Discussions

An organic solar cell (OSC) having the structure “Glass/ITO/PEDOT: PSS/P3HT: PCBM/Al” has been investigated in this work.

Figure 1 shows the device structure to describe the theory of Optical Transfer Matrix Method (OTMM), as per theory in literature, light is incident from air to layer-1 and proceeds, OTMM theory defines the material after the last layer (layer-m) as the substrate, which is thick, no reflected light inside the substrate. In the device structure concept, the “Glass” layer is usually called the substrate since the whole device is built on it. The “substrate” in OTMM theory is not the same as “substrate” in the device structure concept. In the above-mentioned device structure, light is incident on the glass and proceeds, if we apply the OTMM equation in the same direction of light, Al will be the last layer, the “air” after Al layer will be considered as the substrate, the (m + 1)th layer for calculation.

The refractive index (\( \eta \)), extinction coefficient (\( \kappa \)), and the thickness of the layers are used to calculate interface matrices and layer matrices by Equation (1) and Equation (2) defined by the Optical Transfer Matrix Method (OTMM). Then the elements of these matrices and the solar irradiance (I_0) are used to calculate generated excitons by the derived analytical equation. Then charge carriers, current, power, etc. are calculated by the corresponding analytical equations using these excitons. Thus, the derived analytical equations include the device structure size, material property, and solar light intensity in the calculation of OSC performances.
Spectral values of $\eta$ and $\kappa$ of the materials, used for the OSC device, have been collected from literature [31].

The solar light intensity of a place depends on whether the Sun is at the vertical position or at an inclined position relative to that place, the inclination is represented by an index, called air mass (AM). Like many other researchers [2,3,7,8,11,14,20,21], this work has used solar irradiance of AM 1.5 (global) taken from standard source (ASTM G-173-03) [39].

The Equation (18), derived from OTMM, provides the generation rate of excitons as the function of position ($x$) and wavelength ($\lambda$). The equation requires $I_0$ with the unit of $\text{Wm}^{-2}$; however, in the standard dataset [39], irradiance $I_0$ is recorded with the unit $\text{Wm}^{-2}\text{nm}^{-1}$ (i.e., $\text{Wm}^{-2}$ per nanometer bandwidth of wavelength), therefore, for calculating photo-excited part of any quantity (exciton, charge carrier, current) integration with respect to $\lambda$ for the range of effective wavelengths is needed; when integrated wrt $\lambda$, then $d\lambda$ (which has the unit nm) cancels $\text{nm}^{-1}$ part of $\text{Wm}^{-2}\text{nm}^{-1}$ then $I_0$ carries the required unit $\text{Wm}^{-2}$ and hence the calculated (integrated) quantity is obtained with the standard unit.

Regarding the wavelength range, for the analysis of similar devices, some groups [11] used the wavelength range of 350–800 nm; some others [27] used the range of 350–850 nm; in this work, the wavelength range of 350–850 nm has been used.

To see the effects of optical phenomena on the exciton generation, and hence to see the suitability of using OTMM, the spatial distribution of excitons has been investigated. For a position inside the active layer, total exciton for all wavelengths has been evaluated by integrating the exciton obtained using OTMM based Equation (18) over the wavelength range of 350–850 nm. Similarly, the total excitons for all positions have been evaluated and hence the spatial variation of excitons has been obtained. Figure 3 shows the spatial variation of exciton generation rate inside active layer of OSC shown in Figure 2a with the irradiance of 1000 $\text{W/m}^2$ for active layer thickness ($d_j$) of 70, 100, 150, 250, 500, 1000 nm. The result of OTMM shows wave-like (pulsating) variation of exciton generation rate with the position; due to interference of incident light and reflected light the light intensity becomes stronger or weaker at places and hence pulsating variation of excitons occurs. The figure also shows that as the active layer thickness increases, the variation pattern changes from pulsating nature towards decreasing nature. When active layer thickness is very large, the variation exhibits an exponentially decreasing nature which is the same as stated by Beer-Lambert law; the agreement with “law” validates the use of the OTMM. The peak value of exciton generation rate is found in the range of $8 \times 10^{27} - 20 \times 10^{27} \text{ s}^{-1}\text{m}^{-3}$ ($\approx 8-20 \text{ s}^{-1}\text{nm}^{-3}$). The pattern of variation and level of values are consistent with the reported results [10,17,40]. The pulsating variation confirms the effects of optical phenomena, that is, OTMM provides the correct profile of excitons considering optical phenomena and hence suitable for thin layered OSC research.
To find the appropriate dissociation probability, it has been calculated by Equation (19) using dissociation rate \( k_{\text{diss}} \) of Braun’s formula given in Equation (20) and \( k_{\text{diss}} \) of Wojcik’s formula given in Equation (22) and then calculated by Equation (23) incorporating Gaussian distribution function. Some researchers [8,11,29,30] used Braun’s formula and some others [21,25] used Wojcik’s formula, they used a constant value of separation distance \( r_0 \) between electron and hole of an exciton, however, the separation distance value, used in the calculation, should be a representative value for all excitons, we may perceive \( r_0 \) as the average value. To find the appropriate value, the separation distance \( r \) has been taken as a variable (not constant) and dissociation probability has been calculated using Braun’s formula and Wojcik’s formula. Figure 4a shows the variation of dissociation probability with separation distance \( r \) for four-terminal voltages \( V_{a} \) of 0 V, 0.2 V, 0.4 V, and 0.6 V, calculated using Wojcik’s formula. For a certain \( V_{a} \) (i.e., certain field), with the increase of separation distance \( r \), dissociation probability is found to increase from zero to unity. This is logical because when the separation distance is larger, electron-hole-pair (EHP) of that exciton is loosely bounded, hence more feasible to dissociate, therefore, higher dissociation probability. Now the question is, which value of dissociation probability (i.e., which value of separation distance) should be used? The probability increases almost linearly from 0 to 1, hence the average (middle) value of probability (0.5) may be accepted as the representing value for probability; therefore, its separation distance may be assumed as the average separation distance and may be accepted as the representative value for \( r \). However, we see in Figure 4a that the probability value of 0.5 happens with a smaller \( r \) for a smaller \( V_{a} \) and vice versa. This is also logical because we know field \( F = (V_{a} - V_{bi})/d_{j} \). We know \( V_{a} \) increases from zero, when \( V_{a} \) becomes equal to \( V_{bi} \), the field becomes zero, the solar cell stops to charge the external battery, that is, \( V_{a} \) cannot be larger than \( V_{bi} \) the field cannot be positive, the field is always negative (hence current is negative). When \( V_{a} = 0 \), field magnitude is the largest, when \( V_{a} \) increases from zero, field magnitude decreases. For smaller \( V_{a} \), field magnitude is larger which becomes capable to dissociate EHP with lower separation distance (even they are strongly bounded) and hence the probability of 0.5 occurs at lower \( r \). Similarly, for larger \( V_{a} \), the probability of 0.5 occurs at higher \( r \). The separation distances, corresponding to the probability of 0.5, have been investigated for solar cell working range \( V_{a} = 0 - 0.6V \); the average of these separation distances has been obtained as 1.51 nm, which may be used as the
representative value for $r$ in calculation; this average value (1.51 nm) is consistent with the constant value used for separation distance in previous works [21,25].

However, the concept of using a constant value of $r$ assumes that all excitons have the same separation distance, again, the concept of using the average value of $r$ assumes that the population of excitons would be the same at all separation distances; but both these assumptions are not compatible because naturally separation distances would be different and also population would be different.

To commensurate with the natural situation, spherically averaged Gaussian distribution (SAGD) may be incorporated in the calculation of dissociation probability as in Equation (23). For every separation distance ($r$), the probability value (calculated by Braun’s formula or Wojcik’s formula) is multiplied with the SAGD function value at that separation distance to obtain SAGD incorporated probability. Figure 4b shows the SAGD incorporated probability versus $r$ for four-terminal voltages ($V_a$) of 0 V, 0.2 V, 0.4 V, and 0.6 V, calculated using Wojcik’s formula incorporated with the SAGD function. Note that Figure 4b shows the plotting of the integrand of Equation (23) and it has the unit of m$^{-1}$.

The dissociation probability has been calculated by using Braun’s formula, Wojcik’s formula, and Wojcik’s formula incorporating SAGD function and compared; Figure 5 shows the comparative picture of the probability with the variation of $V_a$ for solar cell operation range ($V_a = 0$–0.6 V). For Braun’s and Wojcik’s formulae, the separation distance of $r_0 = 1.5 \times 10^{-9}$ m has been used. To obtain the overall value of SAGD incorporated probability, Equation (23) needs to be integrated, that is, the curve in Figure 4b needs to be integrated. The integrand of Equation (23) is not integrable analytically, the integration has been computed numerically. Ideally, the integration range should be $r = 0$ to $\infty$. From the analysis it was found that for $r = 10^{-11}$ m or less, the value of the integrand is negligible (order of $10^{-300}$) compared to the highest value (order of $10^5$), similarly, for $r = 6 \times 10^{-9}$ m or more, the value of the integrand is negligible, therefore, numerical integration has been carried out for the range $r = 10^{-11}$ m to $6 \times 10^{-9}$ m.
Figure 5. Comparison among the probabilities obtained by Braun’s formula, Wojcik’s formula, and Wojcik’s formula incorporating SAGD function for solar cell operation range ($V_a = 0 – 0.6$V). The probability decreases with $V_a$.

For all three methods, the overall probability was found to decrease with the increase of $V_a$. This is logical because, with the increase of $V_a$, the field magnitude decreases, hence the dissociation probability decreases.

For solar cell operation range, i.e., for $V_a = 0–0.6$ V, Braun’s formula, Wojcik’s formula, and SAGD incorporated formula provide the dissociation probability values of 0.63–0.86, 0.36–0.67, and 0.62–0.72, respectively. For a similar device (P3HT:PCBM-based), some researchers [41] reported the dissociation probability of 0.4–0.74 for $V_a = 0–0.6$ V with constant separation distance. Some other works [42,43] reported the dissociation probability as the function of effective voltage. As the externally applied voltage and internal built-in voltage work in the opposite direction, the effective voltage may be defined as, $V_{\text{eff}} = V_{bi} - V_a$; in this work, $V_{bi}$ is 0.8 V, therefore, for solar cell operation range, $V_{\text{eff}} = 0.2–0.8$ V. For the same range of $V_{\text{eff}}$, Tan et al. [42] reported a probability of 0.6–0.78 and Hao et al. [43] reported a probability of 0.5–0.8. The dissociation probability values obtained in this work are consistent with the values reported in other works. Figure 5 shows that Braun’s formula provides a higher value of dissociation probability, Wojcik’s formula provides a lower value and SAGD incorporated calculation gives the value in between them. The SAGD incorporated probability is thought to be most appropriate because of considering naturally expected population variation of excitons, therefore, this probability has been used in this work.

The current-producing electron density per unit volume ($n$) has been calculated by using Equation (35) which is the analytical solution of the differential Equation (28), then analytical results have been compared with those obtained by numerical solution of the same differential equation. Similarly, current-producing hole density ($p$) has been calculated using analytical Equation (49) and compared with the numerical result. Figure 6a,b show the variation of current producing electron and hole density with the positions inside active layer for OSC having an active layer thickness of 100 nm operated at $V_a = 0.3$ V with an irradiance of 100 mW/cm$^2$. Analytical results (solid lines) are exactly matched with numerical results (markers); this indicates that analytical solutions (expressions) are correct. The charge carrier density for the stated condition is found to vary in the order from $10^{20}$ m$^{-3}$ to $10^{24}$ m$^{-3}$ inside the active region as shown in Figure 6, the average value is in the order of $10^{23}$ m$^{-3}$. For a similar device, some researchers [44] reported a charge density of $6\times10^{15}$ cm$^{-3}$ ($= 6\times10^{21}$ m$^{-3}$); another group [45] reported a charge density in the range from $10^{21}$ m$^{-3}$ to $10^{23}$ m$^{-3}$; the charge density in this work is found consistent
with previous reports. Note that, for numerical solution of differential equation, “bvp4c” solver, a built-in routine of MATLAB, has been used.

![Figure 6](image-url)

**Figure 6.** Analytical and numerical results of current-producing electron density and hole density per unit volume for the OSC with an active layer thickness of 100 nm, irradiance 100 mW/cm², terminal voltage 0.3V.

For a certain device [22], the total current density has been analytically calculated using Equation (61) at different values of $V_a$ for four levels of irradiance 100, 80, 60, and 40 mW/cm², and the analytical results have been plotted along with experimental values. The analytical and experimental results [22] are in good agreement as shown in Figure 7a. Again, the dark component of current has been calculated by the summation of the dark current due to electron by using Equation (43) and dark current due to hole by using Equation (57). Similarly, the photo-excited component has been calculated by the summation of the photocurrent due to electron by using Equation (44) and photocurrent due to hole by using Equation (58). The extracted dark current and photocurrent for the irradiance of 100 mW/cm² have been presented in Figure 7b. The separation of dark current and photocurrent gives a better view than the plotting of total current only.

![Figure 7](image-url)

**Figure 7.** (a) Analytically calculated current density (solid line) and experimental results of current density (circular marker) [22] for four levels of irradiance 100, 80, 60, and 40 mW/cm²; (b) Extraction of dark current and photo-excited current for the irradiance of 100 mW/cm² by using analytical calculations.
The analytical calculations in this work have been carried out using some parameters with the standard values and some others as fitting parameters, whose values have been found while fitting analytical results with experimental ones.

Standard values are: \( \varepsilon_r = 3.5 \), \( \varepsilon_{vac} = 8.854 \times 10^{-12} F/m \), \( c = 3 \times 10^8 \text{ms}^{-1} \), \( h = 6.626 \times 10^{-34} J s \), \( k_B = 1.38 \times 10^{-23} J K^{-1} \), \( S_r = 0.05 \times 10^{-2} \text{ms}^{-1} \), \( q = 1.6 \times 10^{-19} \text{C} \), \( k_B = 1.38 \times 10^{-23} J K^{-1} \), \( V_{bi} = 0.8 V \), \( T = 300 K \), \( \phi_1 = 0.1 V \), \( \phi_2 = 0.9 V \), \( \phi_3 = 0.1 V \), \( \phi_4 = 0.9 V \). The fitting parameters are: \( \mu_\mu = 7 \times 10^{-8} \text{m}^2\text{V}^{-1}\text{s}^{-1} \), \( \mu_p = 0.1 \times 10^{-8} \text{m}^2\text{V}^{-1}\text{s}^{-1} \), \( r_a = 1.65 \times 10^{-9} m \), \( r_m = 5 \times 10^4 \text{s}^{-1} \), \( N_C \), \( N_V = 1 \times 10^{26} \text{m}^{-3} \).

The parameter values are consistent with previous works [18,19,29,31,46,47]. For such work, the calculation must consider recombination, exciton generation, dissociation probability of excitons; these factors cannot be left out. Some researchers neglected recombination, some used constant exciton generation, some used constant separation distance between electron and hole of the exciton to calculate dissociation probability, no work used these factors together. However, this work includes all these factors together, moreover, it uses an improved estimation of excitons and dissociation probability, such as, it uses recombination, OTMM based exciton generation to account for different excitons at different positions, SAGD incorporated dissociation probability to account for the difference in separation distances, therefore, the parameter values extracted in this work are expected to be better, that means, calculation using these parameters would predict OSC performances more accurately, for any irradiance other than the investigated irradiances.

The effects of irradiance on the external properties (\( V_{OC} \), \( J_{SC} \), FF, PCE) of OSC have been investigated by calculating them analytically for different irradiance levels and compared with experimental values [22]. The external properties are found to vary with irradiance as shown in Figure 8; the analytical and experimental results are found consistent. The magnitude of \( J_{SC} \) increases with irradiance as shown in Figure 8a, this is expected because higher irradiance will produce a larger current. \( V_{OC} \) changes with irradiance as shown in Figure 8b. Theoretically [48,49] \( V_{OC} \) may be calculated by the equation, \( V_{OC} = \frac{1}{q} \left( E_{\text{Accepter LUMO}} - E_{\text{Donor HOMO}} - k_BT \ln(N_e N_h) + k_BT \ln(np) \right) \). Here PCBM is acceptor with \( E_{\text{Accepter LUMO}} = -4.2 eV = -6.72 \times 10^{-19} \text{Joule} \) and P3HT is donor with \( E_{\text{Donor HOMO}} = -5.2 eV = -8.32 \times 10^{-19} \text{Joule} \). For irradiance 1000 W/m\(^2\), average \( n \) has been calculated as 1.1025 \times 10^{23} m^{-3} and average \( p \) as 1.4994 \times 10^{23} m^{-3} and then using this \( n \) and \( p \) in the above theoretical equation, the value of \( V_{OC} \) has been found as 0.65V, which is very consistent with the value 0.61 V found by analytical calculation in Figure 8b. \( V_{OC} \) exhibits negligible dependence on irradiance, this can be explained with the above theoretical equation. In the equation, all quantities are constant except \( n \) and \( p \). With the change of irradiance, \( n \) and \( p \) change but not with the order (level), therefore, the logarithm of \( np \) does not change much with irradiance, as a result, \( V_{OC} \) does not change much. Similarly, FF has negligible dependence on irradiance as shown in Figure 8c. PCE increases with irradiance as in Figure 8d. The power loss inside the device mostly depends on the material and not on irradiance, that is, power loss is almost constant for any level of incident power. If we calculate loss percentage with respect to low incident power, loss percentage would be higher, hence, efficiency would be lower. On the other hand, for higher incident power, loss percentage would be lower, hence, efficiency would be higher. These trends of variation and level of values for these properties of OSC are consistent with the reported results [13,14,44,46].
Figure 8. Analytical (solid line) and experimental (marker) [22] results of short circuit current (Jsc), open circuit voltage (Voc), fill factor (FF), and power conversion efficiency (PCE) with the variation of irradiance.

The internal properties (absorbance, EQE, and IQE) of OSC have been analyzed by calculating them by analytical expressions developed earlier. Absorbance has been calculated by using the analytical Equation (62). Average photocurrent $J_{ph,avg}$ has been calculated by using Equation (63) and then EQE by Equation (64). Again, IQE has been evaluated by using absorbance and EQE in Equation (65). These equations provide the result for a single wavelength. Similarly, by calculating internal properties for different wavelengths, the spectral variations of the internal properties have been obtained. Figure 9 shows the spectral variation of absorbance, EQE, and IQE for active layer thickness 100 nm and irradiance 1000 W/m². The analytical results fully matched with numerical results as shown, this indicates that these analytical equations are correct. For absorbance, the variation pattern and level of values are consistent with the reported results of such devices [34,50–54]. A similar shape is also observed for EQE which is consistent with reported works [6,50,53,54].

As absorbance and EQE have the almost same shape and IQE = EQE/absorbance, the shape of IQE is almost constant with the wavelength as shown in Figure 9, a similar constant shape of IQE is also observed by others [52].
The effects of variation of active layer thickness on the generation rate of excitons and charge carriers have been investigated as follows. For a certain value of active layer thickness \( d_j \), exciton generation rate has been calculated by using Equation (18) for a certain position and a certain wavelength; thus calculated for all positions inside active layer and all wavelengths. Then for a certain position, the results of all wavelengths have been integrated to get the effects of all photons; thus, calculated for all positions. Then the results of all positions have been integrated to get total excitons; when the exciton generation rate (unit: \( \text{s}^{-1}\text{m}^{-3} \)) is integrated with the position for the range of 0 to \( d_j \), it gives exciton generation rate per unit area (unit: \( \text{s}^{-1}\text{m}^{-2} \)); this represents the number of excitons generated per unit time in the volume covering a unit area of incident-surface and length of whole active layer thickness. Such calculation of exciton generation rate per unit area has been carried out for several values of \( d_j \). Then charge carrier generation rate per unit area has been calculated by the product of exciton generation rate and dissociation probability. Figure 10 shows the generation rate per unit area versus \( d_j \) for both excitons and charge carriers. Both show deep ripples at lower values of \( d_j \) and shallow ripples at higher values of \( d_j \). For some \( d_j \), the interaction of incident and reflected light would be additive intensive and hence the generation would be high; whereas, for some \( d_j \), the interaction would be subtractive intensive, and hence the generation would be low; therefore, the ripple. The overall trend of variation is, the exciton (per unit area) increases with \( d_j \), this is because of the large space available for photon absorption. On the other hand, charge carrier = \( \text{(exciton)(probability)} \). We know, field \( F = (V_a - V_b)/d_j \), for a certain \( V_a \), with the increase of \( d_j \), field decreases, and hence probability decreases. That is, with the increase of \( d_j \), charge carrier has two effects: increasing effect of exciton and decreasing effect of probability; for a large value of \( d_j \) these two effects are nullified by each other, and hence charge carrier curve increases at a low rate, that is, almost flat as shown. This result is consistent with the results of current density, photons absorbed, the efficiency with the variation of active layer thickness obtained by other researchers [14,31,32,49].

**Figure 9.** Spectral variation of absorbance, EQE, and IQE for OSC with the irradiance of 1000 W/m².
We know, electrons and holes per unit volume is used for calculating the current, therefore, the charge carrier generation rate per unit volume needs to be investigated. As the generation rate per unit area indicates the amount in the volume covering a unit area of incident surface and length of whole active layer thickness, if we divide the generation rate per unit area by the active layer thickness then it will represent the amount in the volume of unit area and unit length, i.e., the average amount in unit volume, thus the average generation rate per unit volume (unit: $s^{-1}m^{-2}$) has been determined by dividing the generation rate per unit area by $d_j$, a similar calculation has been done for all values of $d_j$. Figure 11 shows the generation rate per unit volume versus $d_j$ for both excitons and charge carriers. With the increase of $d_j$, generation rate per unit volume has two effects: increasing effect of overall generation rate per unit area and decreasing effect due to division by $d_j$; at the low range of $d_j$, increasing effect is more, hence generation rate per unit volume increases; at $d_j$ around 60 nm both effects become equal and the generation rate reaches to maximum, for $d_j$ more than 60 nm, decreasing effect becomes dominant, hence generation rate per unit volume decreases as shown in Figure 11.

Some previous work [21] calculated J-V for $d_j = 70$ and 150 nm; some work [25] calculated J-V for $d_j = 80, 100, 120,$ and $140$ nm; these works showed that current decreases with the increase of $d_j$; the present study also supports those previous results because we see that in the similar range (70–150 nm) of $d_j$, exciton (or charge carrier) generation rate per unit volume decreases with the increase of $d_j$, which is shown by the box in Figure 11. However, there are some range of $d_j$ for which exciton (or charge carrier) increases with the increase of $d_j$ or remains almost constant as shown in Figure 11, that is, the trend of decreasing current with the increase of $d_j$ would not be true for all range of $d_j$, that means, this study provides a better and bigger picture regarding the effect of variation of $d_j$. From this analysis, it is seen that the generation rate per unit volume is the highest for the active layer thickness of 60 nm, therefore, it might be predicted that OSC would provide the highest performance with the active layer thickness of 60 nm. In the literature, we see that many research groups fabricated OSC having an active layer thickness of 100 nm (which is close to 60 nm); may be, they did not go with a lower thickness because of the fabrication challenge.
Maximum power \( (P_{\text{max}}) \) has also been investigated with the variation of active layer thickness; \( P_{\text{max}} \) is found to vary with active layer thickness as shown in Figure 12, which has been obtained for irradiance of 1000 W/m\(^2\). The variation pattern is similar to that of the charge carrier generation rate per unit volume shown in Figure 11. Charge carrier per unit volume determines the current and hence the power, therefore, the similar shape. For such a device with \( d_j = 100 \) nm, experimental \( P_{\text{max}} \) has been calculated from experimental J-V [22] and plotted along with analytical \( P_{\text{max}} \) results; the experimental result matches the analytical result for \( d_j = 100 \) nm. For calculating \( P_{\text{max}} \) analytically with \( d_j \) other than 100 nm, the only \( d_j \) has been changed keeping all other parameters the same, therefore, we may expect that analytical \( P_{\text{max}} \) results with other \( d_j \) will also match with the experimental \( P_{\text{max}} \) for the same device.

Comparing with previous work on OSC, this work is expected to provide a better result with a bigger view and clear understanding. This is because this work has been done to shed light on the following matters: (1) detail derivations of analytical expressions of excitons, charge carriers, electrons, holes, current, absorbance, EQE, IQE; (2) investigation of the spatial distribution of excitons inside the active layer of OSC; (3) investigation of separation distance and dissociation probability; (4) improved analytical computation of OSC properties using OTMM-based excitons, SAGD incorporated probability and recombination altogether; (5) investigation of the effects of variation of irradiance on J\(_{\text{sc}}\), Voc, FF, PCE; (6) spectral analysis of absorbance, EQE, IQE; (7) investigation of the effects of variation of active layer thickness on exciton, charge carrier and \( P_{\text{max}} \).

This work might be utilized for further improvement of OSC, for example, to decide about active layer thickness for obtaining the highest performance. The same calculation approach may be applied to study the optimization of other layer thickness, the replacement of layer materials for the betterment of OSC performances such as the widening of spectral absorption, increasing the efficiency, etc.

**Figure 11.** Generation rate per unit volume versus active layer thickness for excitons and charge carriers.
Figure 12. Variation of maximum power with the variation of active layer thickness with the irradiance of 1000 W/m².

7. Conclusions

Photo-generated excitons inside the organic solar cell (OSC) have been calculated using the optical transfer matrix method (OTMM), this shows the pulsating variation with positions inside the active layer having a peak value of $8 \times 10^{27} - 20 \times 10^{27}$ s⁻¹m⁻³, due to the effect of optical phenomena. While calculating the charge carriers from excitons, spherically averaged Gaussian distribution (SAGD) incorporated dissociation probability has been found most logical and appropriate. OSC performances have been calculated by analytical equations derived by solving electrical transport equations including OTMM based excitons, SAGD incorporated dissociation probability, and recombination of charge carriers, all together. Analytical results of current producing electrons, holes, J-V, Jsc, Voc, FF, PCE, absorbance, EQE, IQE are found to match with numerical and experimental results and consistent with previous works. Exciton and charge carrier generation rate per unit area are found to increase with active layer thickness. Whereas, exciton and charge carrier generation rate per unit volume and $P_{\text{max}}$ increase, reach to the top and then decrease with active layer thickness; the highest performance at an active layer thickness of 60 nm; these are also found consistent with previous results. The matching of analytical results with numerical results indicates the correctness of analytical expressions, matching with experimental results indicates the capability of predicting OSC properties, and consistency with previous works ensures the validity of the analytical computational results. Compared to previous analytical works on OSC, the results in this work are expected to be more accurate because of including the above-mentioned 3 factors together in the analytical solution. Moreover, calculating OSC performances by the analytical expressions in this work is easy because the expressions are simple and only involves the summation of exponential, sine, and cosine terms. The results of detail analysis are expected to be useful for designing improved OSC and the detailed derivations of analytical expressions are expected to help the readers to understand the OSC research with more insight.

Appendix A

Let us find $E_j^+(x)$ and $E_j^-(x)$. We may assume, $E_j^{+'}$ and $E_j^{-'}$ are the forward and backward field components at the beginning of $j^{th}$ layer (Figure 1). Here $E_j^{+'}$ starts from the left boundary ($x = 0$); when it reaches position $x$, it becomes $E_j^{+'} \exp(i \xi_j x)$, which is represented by $E_j^+(x)$, that is, $E_j^+(x) = E_j^{+'} \exp(i \xi_j x)$. Similarly, for the backward direction, $E_j^-(x)$ starts from the position $x$; when it reaches the right boundary ($x = 0$), it becomes $E_j^-(x) \exp(i \xi_j x)$, which is represented by $E_j^-(x)$, that is, $E_j^-(x) = E_j^{-'} \exp(i \xi_j x)$.

Putting the above expressions of $E_j^+(x)$ and $E_j^-(x)$ in Equation (7) we get Equation (8).

Appendix B

Let us find $t_j^+$. We may define an internal forward transfer coefficient ($t_j^+$) as $t_j^+ = E_j^+/E_j^0$, hence we get $E_j^{+'} = t_j^+ E_j^0$. Again, $E_j^{+'}$ starts from left boundary; when reaches at the right boundary, it becomes $E_j^{+'} \exp(i \xi_j x)$; after reflection at the right boundary, leftward field is $E_j^{+'} \exp(-i \xi_j x)$; when reaches at the left boundary, it becomes $E_j^{+'} \exp(i \xi_j x) E_j^{+'}$ or $E_j^{+''} \exp(i 2 \xi_j x)$, which is represented by $E_j^{-'}$, that is, $E_j^-' = E_j^{+''} \exp(i 2 \xi_j x)$ or $E_j^-' = E_j^{+''} \exp(i 2 \xi_j x)$. Putting the above expressions of $E_j^{+''}$ and $E_j^-'$ in Equation (8) we get Equation (9).

Appendix C

Let us find $t_j^+$. Like the Equation (4), $E_0^+$ and $E_0^-$ may be related with $E_j^{+'}$ and $E_j^{-'}$ via $S$ and hence we may get $E_0^+ = S_{11} E_j^{+'} + S_{12} E_j^{-'}$ that results $E_0^+ / E_j^{+'} = S_{11} + S_{12} E_j^{-'} / E_j^{+'}$. Since $E_j^{+'} = E_j^{+''} \exp(i 2 \xi_j x)$ or $E_j^{-'} / E_j^{+'} = r'' \exp(i 2 \xi_j x)$, therefore, $E_0^+ / E_j^{+'} = S_{11} + S_{12} r'' \exp(i 2 \xi_j x)$. Using the above expression of $E_0^+ / E_j^{+'}$ we may get the expression of $t_j^+$ as in Equation (10).

Appendix D

Putting $\eta = \eta_j + i \kappa_j$ in Equation (11) and assigning $\beta_1 = \exp(-2 \pi \kappa_j x / \lambda)$, $\beta_2 = \exp(-2 \pi \kappa_j (2d_j - x) / \lambda)$, $\beta_3 = \exp(-2 \pi \kappa_j (2d_j - x) / \lambda + \delta''$ we obtain

$$E_j(x) = t_j^+ E_0^+ [\beta_1 \exp(i \eta_1) + \beta_2 \exp(i \eta_2)]$$

$\Rightarrow E_j(x) = t_j^+ E_0^+ [\beta_1 \exp(i \eta_1) + \beta_2 \exp(i \eta_2)]$  \hspace{1cm} (A1)

The absolute value of $E_j(x)$ can be found as

$$|E_j(x)|^2 = |t_j^+|^2 |E_0^+|^2 \left[ (\beta_1 \cos \theta_1 + \beta_2 \cos \theta_2)^2 + (\beta_1 \sin \theta_1 + \beta_2 \sin \theta_2)^2 \right]$$

$\Rightarrow |E_j(x)|^2 = |t_j^+|^2 |E_0^+|^2 \left[ \beta_1^2 + \beta_2^2 + 2 \beta_1 \beta_2 \cos(\theta_1 - \theta_2) \right]$ \hspace{1cm} (A3)

$|E_j(x)|^2 = |t_j^+|^2 |E_0^+|^2 \left[ \exp(-\alpha x) + \exp(\alpha x) + M \cos(N - Rx) \right]$ \hspace{1cm} (A4)

where, $\alpha_j = 4 \pi \kappa_j / \lambda$; $L = \rho'' \exp(-2 \alpha_j d_j)$; $M = 2 \rho'' \exp(-\alpha_j d_j)$; $N = (4 \pi \eta_j d_j / \lambda + \delta'')$; $R = 4 \pi \eta_j / \lambda$.}

Appendix E

Irradiance (I) is the power per unit area. To derive the equation of I, we may start with parallel plate capacitor energy and its electric field. Capacitor energy = (1/2)CV^2=
(1/2)(εA/d)V^2 = (1/2)(εAd)(V/d)^2 = (1/2)ε(Volume)(E)^2. Hence, we get, Energy/Volume = (1/2)εE^2. Light with speed c, falling on a material having surface area A1, will provide optical energy to a volume of A1ct_1 of the material during time t_1. Energy in a volume = (Energy/Volume) × Volume = (1/2)εE^2 × A1ct_1. Now, Power = Energy/Time = (1/2)εE^2 × A1c. Then, Irradiance I = Power/Area = (1/2)ceE^2.

Appendix F

Now, incident irradiance I_0 = (1/2)c|ε₀E_0|^2 that results |E₀|^2 = (2I₀/c_₀ε₀). Again, according to Maxwell, light speed c = (με)^{-1/2} = (u_νε με)^{-1/2}; where μ = magnetic permeability. For non-magnetic material, c_ν = 1, therefore, c = (με με)^{-1/2}. Accordingly, c_j = (με_νε νε)^{-1/2} and c_ν = (με_νε νε)^{-1/2}. Again, for such non-magnetic material, the refractive index η = c_νε/c = (με_νε νε)^{-1/2} = (με_νε νε)^{-1/2} = (με_νε νε)^{-1/2} = (ε_j)^{1/2}. Accordingly, η_j = (ε_j/ε_νε νε)^{1/2} and η_ν = (ε_νε νε)^{1/2}, hence η_j/η_ν = (ε_j/ε_νε νε)^{1/2}. Using the above relations in Equation (14), we can get Equation (15).

Appendix G

 Naturally, the separation distances (r) will be different for different excitons because of the difference in photon energy. Depending on the material used in the device, a specific separation distance (r = r₀) would be most feasible and hence the number of excitons with that separation distance would be the highest; for other separation distances (r < r₀ or r > r₀) the excitons would be less. This phenomenon may be addressed by giving different weights to the probability corresponding to different separation distances by using a standard distribution function of Gaussian distribution (SAGD) function may be used and hence the probability (P) may be calculated by Equation (23).

Appendix H

Many researchers found the active layer thickness of 100 nm suitable for making a good performance OSC; constant field assumption works well until 200 nm thickness; therefore, this assumption would be acceptable for most of the available OSC devices. Again, due to the difference in mobility of electron and hole, the charge transport may become unbalanced, as a result, a net space charge may build-up, this space charge may affect the electric field, this effect has been assumed negligible. These assumptions regarding the electric field have been considered to obtain a complete analytical solution. Again, monomolecular recombination has been included because this allows us to obtain a complete analytical solution. The analytical solution would not be possible for bimolecular recombination. In the situation where these assumptions would not be valid, we have to use numerical computation.

Appendix I

The particular solution of the differential Equation (31) is

\[ n_{ph2} = \frac{1}{(D^2 + a_1D + a_2)}a_3G \]

where, \( D \equiv \frac{d}{dx} \)

Using G from Equation (25) which is for single wavelength, we obtain

\[ n_{ph2} = \frac{1}{(D^2 + a_1D + a_2)}a_3KH(x) = \frac{1}{(D^2 + a_1D + a_2)}a_3K[\exp(-a_1x) + L\exp(a_1x) + M\cos(N - Rx)] \]

\[ \Rightarrow n_{ph2} = a_3K[a_4\exp(-a_1x) + a_5\exp(a_1x) + a_6\cos(N - Rx) + a_7\sin(N - Rx)] \]

\[ (A7) \]
where, 
\[ a_4 = \frac{1}{(a_j^2 - a_j a_j + a_2)} \]  
\[ a_5 = \frac{L}{a_j^2 + a_j a_j + a_2} \]  
\[ a_6 = \frac{M(a_2 - R^2)}{(a_2 - R^2)^2 + a_3^2 R^2} \]  
\[ a_7 = \frac{-M a_4 R}{(a_2 - R^2)^2 + a_3^2 R^2} \]

**Appendix J**

At \( x = 0 \), electron concentration [12,36]: 
\[ n_{\mid x=0} = N_c \exp(-\phi_2/V_T), \]  
where \( N_c \) is the effective density of states at PCBM LUMO (= conduction band), \( \phi_2 \) is the electron injection barrier potential at \( x = 0 \) (see Figure 2b), \( V_T = k_B T/q \) is the thermal voltage. Applying this boundary condition to Equation (35) we obtain

\[ N_c \exp(-\phi_2/V_T) = n_{\text{dark}}|_{x=0} + \int_{A_1}^{A_2} n_{\text{ph}}|_{x=0} d\lambda \]

(A9)

At the boundary position (\( x = 0 \)), electron concentration depends on electron injection barriers, photoexcitation cannot change this electron injection barrier, that is, electron concentration at the boundary does not depend on photon (\( \lambda \)). Therefore, the \( \lambda \)-related part at the right side of Equation (A9) should be equal to zero, and hence the constant part at the right side should be equal to the constant part at the left side. That is,

\[ \begin{align*}
\text{Constant part:} & \quad n_{\text{dark}}|_{x=0} = N_c \exp(-\phi_2/V_T) \\
& \Rightarrow A_1 + A_2 = N_c \exp(-\phi_2/V_T) \\
& \Rightarrow \lambda \text{ Related part:} \int_{A_1}^{A_2} n_{\text{ph}}|_{x=0} d\lambda = 0 \\
& \Rightarrow n_{\text{ph}}|_{x=0} = 0 \text{ [Differentiating wrt } \lambda \text{]} \\
& \Rightarrow A_1 + A_2 = a_8
\end{align*} \]

where, 
\[ a_8 = -a_3 K [a_4 + a_5 + a_6 \cos(N) + a_7 \sin(N)] \]

By solving Equation (A11) and Equation (A17) we get the value of \( A_1 \) and \( A_2 \) written in Equation (36) and Equation (37), respectively.

By solving Equation (A14) and Equation (A20) we get the value of \( A_3 \) and \( A_4 \) written in Equation (38) and Equation (39), respectively.

**Appendix K**
If we divide incident irradiance $I_0$ (unit: $\text{Wm}^{-2} \text{or Js}^{-1} \text{m}^{-2}$) by photon energy $\hbar c/\lambda$ (unit: $\text{J}$) then we will obtain incident photon rate as $I_0\lambda/\hbar c$ (unit: $\text{s}^{-1} \text{m}^{-2}$); as absorbance would be unitless, we need the absorbed photon with the same unit $\text{s}^{-1} \text{m}^{-2}$. Equation (16) gives the absorbed photon rate per unit volume $AP_{vol}$ (unit: $\text{s}^{-1} \text{m}^{-2}$) for a single wavelength. If we integrate $AP_{vol}$ with respect to $x$ from 0 to $d_j$, we will obtain the absorbed photon rate per unit area $AP_{area}$ with the unit $\text{s}^{-1} \text{m}^{-2}$, this will represent the number of photons absorbed per unit time in the volume covering a unit area of incident-surface and length of whole active layer thickness.

$$AP_{area} = \int_0^{d_j} AP_{vol} dx$$  \hspace{1cm} (A21)

$$\text{Absorbance} = \frac{\text{absorbed photon rate}}{\text{incident photon rate}} = \frac{AP_{area}}{(I_0\lambda/\hbar c)}$$  \hspace{1cm} (A22)

After calculating we will get the Equation (62).

**Appendix I**

We should use photocurrent (not dark current) for the calculation of EQE. If we divide photocurrent density (unit: $\text{Am}^{-2}$ or $\text{Cs}^{-1} \text{m}^{-2}$) by the charge value of an electron $q$ (unit: C) then we will obtain photocurrent-producing charge carrier rate with the unit $\text{s}^{-1} \text{m}^{-2}$. Note that, Equation (44) and Equation (58) give the photocurrent density $J_{ph}$ and $J_{pph}$ for a single wavelength. Total photocurrent density $J_{ph} = (J_{nph} + J_{pph})$ is the function of $x$, therefore, the average value $J_{ph,avg}$ is to be calculated, then the photocurrent-producing charge carrier rate can be calculated as $\langle J_{ph,avg}/q \rangle$.

$$J_{ph,avg} = \frac{1}{d_j} \int_0^{d_j} (J_{nph} + J_{pph}) dx$$  \hspace{1cm} (A23)

After calculating we will get the Equation (63).
