Background: Masters athletes (MAs) have led a physically active lifestyle for an extended period of time or initiated exercise/sport in later life. Given the benefits of physical activity and exercise we investigated if body mass index (BMI), an indirect health indicator of obesity, was clinically superior in MAs as compared to controls or the general population.

Methods: Seven databases (Medline, PubMed, Scopus, Web of Science, CINAHL, PsycINFO, Cochrane) were electronically searched for studies on BMI (kg/m²) or as a percentage of BMI categories (underweight, normal, overweight, obesity) in MAs.

Results: Of the initial yield of 7,431 papers, 60 studies met our inclusion criteria and were used in this literature review. Studies identified were classified as: endurance sports (n = 14), runners (n = 14), mixed sports (n = 8), cyclists (n = 4), soccer (n = 4) swimmers (n = 3), non-specific (n = 3), orienteering (n = 2), World Masters Games (n = 2) and individual sports (n = 5). Where BMI was presented for the group of MAs the mean was 23.8 kg/m² (± 1.1) with a range from 20.8 kg/m² (endurance runners) to 27.3 kg/m² (soccer players), this was significantly lower (p < 0.001) than controls (26.13 ± 1.7 kg/m²). Where gender specific BMI was reported the mean for male MAs was 23.6 kg/m² (± 1.5) (range 22.4 kg/m² endurance to 26.4 kg/m² swimmers) and 22.4 kg/m² (± 1.2) for female MAs (range 20.8 kg/m² mixed to 24.7 kg/m² WMG).

Conclusion: In most, but not all studies the BMI of MAs was significantly lower than controls. A clinically superior BMI affords MAs reduced risk with regard to a number of cardiometabolic diseases, osteoarthritis and certain types of cancers.

Key Words: BMI, Veteran athlete, World masters games, Physical activity, Obesity

INTRODUCTION

Globally, the prevalence of overweight and obesity has increased at an alarming rate throughout the world. In Australia, the percentage of adults classified as obese has increased two fold in the past two decades with approximately 11.2 million adults classified as overweight or obese, 42 percent of which are males and 29 percent females [1]. Extensive literature illustrates that there is an elevated risk of developing a number of chronic diseases and disorders with being overweight and obese and these include, dyslipi-
One common clinical measure of overweight and obesity easily attained with no specialized equipment is body mass index (BMI), this mathematical calculation only requires a participant’s mass and height (BMI (kg/m²) = mass (kg)/height squared (m²)). The World Health Organization developed an international classification for BMI and includes normal (18.5 ≤ BMI < 25 kg/m²), overweight (25 ≤ BMI < 30 kg/m²) and obese (BMI ≥ 30 kg/m²). This measure is commonly used in medical and sports medicine research [3].

Master athlete (MA) is a term applied to individuals, typically over the age of 35 who train (exercise) on a regular basis to compete in organized competitive sport. There is no definitive age for master athletes as different sporting organizations define MA at differing ages. For example, swimming MAs start at 25 years (although this in turn can vary between events), however USA Track and Field defines the age for MA as 30 years old yet long-distance runners must be at least 40 years old. There is considerable growth in the number of MAs [4], for example greater than 50% of the male finishers and 40% of female finishers of the New York marathon were MAs [4] and the recent World Master Games (WMG), held quadrennially, attracted 28,676 MAs from 95 countries who competed in 28 different sports [5].

Master athletes have been proposed as a model for successful aging [6]. The benefits of long-term participation in exercise training, whether life-long or adopted in later life, are associated with a number of health benefits which includes decreased health risks associated with various chronic diseases and a reduction of premature death. In our study of WMG MAs [7,8] we have shown a lower BMI as compared to the US and Australian general populations, we believe these findings warranted investigation of BMI in MAs in general. The purpose of this paper was therefore to review the existing published studies on MAs that included BMI as either a primary, secondary or incidental outcome measure. We hypothesized that MAs would have clinically better (i.e. lower) BMIs as compared to a sedentary population or the general population.

**MATERIALS AND METHODS**

All studies considered for this review were required to have Institutional Review approval for the use of human subjects as per the Declaration of Helsinki [9].

1. **Eligibility criteria**

For studies to be included in this review, they were required to be full-length research articles, published in scientific journals (e-publication ahead of print, in hard copy print or online), in English with no limit set on the date of publication. Theses (masters or doctoral) were also considered if the degree had been awarded (conferred) to the higher degree candidate who completed the research. Studies included male and/or female participants so long as the participants were described as master athletes, veteran athletes, World Master Games athletes, Pan Pacific Masters Games athletes, or similar. Each of the studies must have included BMI (kg/m²), gender specific BMI (kg/m²) or a percentage of World Health Organization BMI categories (underweight, normal, overweight, obese) as an outcome variable. Body mass index was not required to be the primary outcome for consideration. Studies were included despite no comparison group or statistical analyses between groups. Studies were also included if the participants were free from disease or had documented disease (i.e., acute myocardial infarction, atrial fibrillation, HTN).

The following exclusion criteria were applied during study selection: abstracts, case studies, conference presentations, conference posters, letters to the editor, book chapters, unpublished papers or papers not in English. Publications that did not evaluate human subjects or have BMI as an outcome variable were excluded from this review.

2. **Search methods**

To identify all relevant published studies, a multistep literature search was conducted from December 2017 to March 2018 without any limits on the date of publication in the following electronic databases: CINAHL (via EBSCO,
Joe Walsh, et al : Body Mass Index in Master Athletes

1982-present), Medline (via OvidSP, 1946-present), PsycINFO (via OvidSP, 1806-present), PubMed (1809-present), Scopus, SPORTDiscus and Web of Science all of which were available from our institutions. Additionally, manual searches of the reference lists of each publication were completed to identify additional studies which possibly met our inclusion criteria. Search terms included the following: BMI, master athlete, older athlete, veteran athlete, World Masters Game(s), Pan Pacific Masters Game(s) and were tailored to the distinctions of the specific database.

3. Data collection and analysis

All search results were exported directly (or manually) into the EndNote (version X8.2) commercially available bibliographic management software program, duplicate records were then removed. Initially, the titles and abstracts were reviewed for possible inclusion or exclusion. Those studies with titles or abstracts warranting review, were subsequently downloaded as full manuscripts to determine if it met the inclusion criteria. The full-text manuscript was then attached to its EndNote citation if it met the inclusion criteria.

The electronic databases search initially retrieved 7,431 records, with four additional records identified through the manual search of reference lists. With duplicates removed a total of 2,824 records were screened for possible inclusion in the literature review. A total of 60 studies met the eligibility criteria and were used in the literature review (Fig. 1).

4. Study characteristics

The 60 studies included in the review were broken down into individual sports (i.e., runners, cycling, orienteering, soccer, x-country skiing, swimming), mixed/non-specified (where participants were from more than one sport or the sport is not specified), endurance (non-specific) and World Masters Games. The total number of master’s athletes included in the 60 studies was 13,095. Study size of master athlete participants ranged from 5 to 1,435 (excluding control or comparison groups). Not all studies provided statistical analysis between groups for BMI, where no analysis was available, we have reported the difference between groups as a percentage (%). Additionally, where there was a non-significant difference between the control group (when sedentary), we have reported the difference as a percentage (%).

RESULTS

The study characteristics of the 60 individual studies are summarized in Table 1 below. Table 1 includes a summary of the manuscript authors, participant characteristics (sports played and participant ages), pertinent study findings and other relevant information of note.

Of the 60 MA studies identified, runners (n = 14) [10-23] and endurance (n = 14) [24-37] categories had the highest number of investigations. This was following by the mixed category with eight studies and cyclists and soccer each with four studies. Swimming and the non-specified category each had three studies and the World Masters Games and orienteering comprised two studies. The remaining MA singular studies included basketball, ice skating, rowing, rugby (union) and cross-country skiing.

We identified a single study [38] that evaluated the BMI in master basketball athletes from the WMG. This was a large cohort study with over 400 participants, the authors compared the MAs BMI according to the World Health Organization [39] classification of obesity (BMI ≥ 30 kg/m²) to the Australian general population (age and gender...

Table 1. Continued

- 291 male athletes
- 250 males
- 41 females
- 126 male short-distance
- 98 female short-distance
- 53 male middle-distance
- 26 female middle-distance
- 116 male long-distance
- 76 female long-distance
- 250 males
- 41 females
- 42 (9) Athletes
- Training 47.5 (4.9) wks/yr
- No statistical analyses between genders for BMI
- European Veteran Championships and World Master Athletic Championships
- No statistical analyses between groups for BMI
- Short < 400 m
- Middle 800-1500 m
- Long > 1500 m
- No statistical analyses between genders for BMI
- 65.2 (28.3) km/d
- 5-10 hrs/wk
- 3000-10,000 m runners who trained regularly for past > 10 yrs
- Training for 27 (10.4) yrs
- 8.4 (1.6) hrs/wk
- Control group was recreational athletes who were in an aerobic training program > 10 yrs
- 29.9-40.3 miles/wk
- No control group
- No statistical analyses between genders for BMI

- No statistics for BMI between groups
matched) given the majority of participants from that WMG were from the host country Australia. Walsh et al. reported the MA basketball players had a significantly (p < 0.01) lower percentage of obesity (based upon BMI) across all age groups (30-40 yrs, 40-50 yrs, 50-60 yrs and 60-70 yrs) as compared to the Australian general population. The difference between groups in percentage obesity ranged from 11.7-14.1% for the MA basketball players and 20.4%-26.9% in the Australian general population. Given the BMI findings in the Walsh et al. study was according to WHO classifications of BMI via additional WHO cut-off points it was difficult to compare to other studies. However a recent study by Gryko et al. [40] reported the BMI of professional adult male basketball players, where mean BMI was in the overweight classification (24.0 kg/m² ± 1.81). The Gryko et al. finding is similar to the average BMI reported for 2016 US male basketball players (24.7 kg/m²) [41] and national basketball league players (1953-2009) (24.08 kg/m²) [42].

There were three papers [43-45] which investigated MA cyclists (n = 75 athletes). The mean BMI for the cyclists (across all three studies) was 23.7 kg/m² (± 1.1) (range 22.3-24.8 kg/m²) compared to 25.1 kg/m² (± 1.0) for controls. In the two studies which utilized a control group, only one study [43] reported a significant (p < 0.01) difference between groups, however the other study by Nicholas and Raugh [46] reported no difference (p = 0.74). The Nicholas and Raugh [46] study did however incorporate active males as controls. The third study by Chilelli and colleagues [45] had no comparison group.

A single [47] study of MA ice skaters (n = 76 athletes) was identified, their mean BMI was categorized as normal at 23.7 kg/m² (± 2.4), unfortunately there was no comparison group. There were two studies [48,49] which investigated master orienteering athletes. Both studies incorporated top-ranked Finnish MA orienteering runners (n = 533) and both studies reported a significantly (p = 0.0008 and p < 0.001) lower BMI in the MAs as compared to controls. The mean BMI classification for the both studies was normal (23.2 and 23.2 kg/m²) while the control groups were classified as overweight (25.5 and 26.8 kg/m²).

There were 14 studies which investigated MA runners [10-23], ranging from 12 to 495 participants, there were a total of 1,575 MAs with a group mean BMI ranging from 20.8 to 24.6 kg/m², all MA runners group means were classified as normal for BMI. Comparatively, the mean controls BMI was 25.7 kg/m² (± 1.5) which is classified as overweight. Only four studies reported BMI specified by gender, males had a mean of 23.1 kg/m² (± 0.5) with females having a significantly lower (p < 0.001) mean of 21.8 kg/m² (± 0.6). Only three of the studies reported significant differences between groups, the studies reporting non-significant differences had the runners mean BMI 3.0 to 10.5% lower than controls.

We identified four studies [50-53] which reported BMI in MA soccer players, only 2 of the studies found a significant difference between groups (MA vs controls), Schmidt et al. [52] utilized healthy, age-matched controls (p = 0.016) while Walsh et al. [53] found a significant (p < 0.05) difference between MA soccer players and the Australian general population. The BMI for MA soccer players ranged from a group mean of 24.6 (normal) to 27.3 kg/m² (overweight).

Despite the popularity of masters swimming, we only identified three studies [54-56] which included MA swimmers. The mean BMI across all three studies for the MA swimmers was 25.0 kg/m² (overweight), range 23.7 kg/m²-25.9 kg/m². Crow et al. [56] compared master pool swimmers to the state of California (USA) general population and found a significant difference between MA swimmer genders (p = 0.024) and between genders in the prevalence of obesity between groups (p < 0.001, MAs vs general population) and between genders and the general population (males p < 0.003; females p < 0.01). Walsh et al. [55] compared MAs competing at the World Masters Games to the Australian general population. A significant difference between MA swimmers genders (p < 0.001) and the Australian general population (p < 0.01) was demonstrated (55).

A single study was identified for each of BMI in MA rowers [57], MA rugby union [58] and MA x-country skiers [59]. Sliwicka and colleagues [57] found a non-significant (p = 0.482) difference between master rowers and active-professional controls; the rowers had a +2.3% higher mean BMI as compared to the control group (25.4 vs 24.8 kg/m³). Climstein and colleagues [58] investigated master
rugby union athletes who participated in the International Golden Oldies World Rugby festival. There was a total of 120 MA rugby players, and they found a significant difference (p < 0.05) in the percentage of obese in the older (≥ 50 yrs) versus younger (< 50 yrs) rugby MAs (37.2 vs 43.0%). There was also a single investigation of male MA x-country skiers. Myrstad et al. [59] found a significant difference (p < 0.001) between MA skiers and aged-matched controls from the general population of Norway (23.6 vs 27.0 kg/m²).

Fourteen studies were identified, which were classified as investigating endurance MAs ranging from 10 to 591 endurance participants. These studies had a cumulative total of 907 endurance MAs with a group mean BMI of 23.6 kg/m² (range 20.4-27.2 kg/m²) whereas controls had a significantly lower (p < 0.001) group mean of 25.6 kg/m² (± 2.1). Only two studies [26,27] reported BMI by gender, where males had a mean BMI of 22.4 kg/m² and females higher (+18.8%) at 26.6 kg/m². Of all MA endurance studies, only five (35.7%) found a significant difference between groups (athletes vs controls), where there was no statistical difference the endurance runners’ BMI was 0.4% to 18.2% lower than controls.

There were eight studies we classified as mixed, these studies included 1,318 MA athletes from mixed sports, study size ranged from 17 to 535. Five of the eight studies resulted in a significant difference between groups however in a study by Sallinen et al. [60], the MAs actually had a significantly higher (p < 0.001) BMI as compared to the controls (middle-aged athletes 29.0 vs 22.7 kg/m² and older athletes 28.4 vs 24.7 kg/m²). Of all MA endurance studies, only five (35.7%) found a significant difference between groups (athletes vs controls), where there was no statistical difference the endurance runners’ BMI was 0.4% to 18.2% lower than controls.

DISCUSSION

The purpose of this review was to examine the BMI in MAs and determine if there was a reduced risk identified in MAs as compared to controls or the general population. It was hypothesized that differences in BMI would exist when MAs were compared to sedentary controls and when compared to the general population. To the authors’ knowledge, this is the first study to thoroughly review BMI in MAs.

Our review identified 60 studies which met our inclusion criteria, this involved a total of 10,061 MAs (73.8% male) and 70,353 controls. The mean BMI of all MA was found to be significantly (p < 0.001) lower than controls (−9.5%, 23.78±1.4 vs 26.13±1.7 kg/m²). Where gender specific MAs BMI was available, females tended (p = 0.126) to have a lower (−4.7%, 22.62±1.2 kg/m²) BMI as compared to males (23.68±1.5 kg/m²).

According to the US National Health and Nutrition survey (N = 17,375) [73] findings, our MAs as a group was lower (−11.4%) than that of the average US adult (23.78...
vs 26.5 kg/m²). This finding is similar to that found when comparing MAs BMI to that of the Australian general population. As a group, MAs were found to have a lower (−17.3%) BMI as compared to the Australian general population (23.78 vs 27.9 kg/m²). This finding was similar with regard to gender specific BMI with male (−23.9%) and female (−22.0%) MAs were lower than the general population.

Seidell and Halberstadt [74] had investigated if a high BMI was actually associated with a lower risk of mortality and increased life expectancy, they found that the relative mortality risk was increased with a BMI of 25 kg/m² however higher BMI was associated with a reduced risk. They further explained that their observation was explained by methodological bias.

Dr Afzal [75] and his colleagues investigated BMI with regard to mortality, they identified the lowest all-cause mortality was associated with a BMI of 26.4 kg/m² (2003-2013, 95% CI, 23.4-24.3 kg/m²) this value is higher than the mean BMI found in our review of MAs. This value was shown to increase by 3.3 kg/m² from 1976 to 2013. Wang and colleagues [76] also investigated BMI with regard to mortality and reported a higher BMI (28.6 kg/m²).

There is substantial literature indicating that a high BMI (overweight and obese) is associated with an increased risk of developing a number of chronic diseases and conditions. Kearns et al. [77] evaluated the risk and determined that the highest risk (risk ratio (RR) in parentheses) was associated with HTN (RR 2.1) followed by osteoarthritis (RR 2.0), T2dm (RR 1.6), hypercholesterolemia (RR 1.3) and low back pain (RR 1.2). With regard to gender specific risk, HTN and osteoarthritis was the highest risk in overweight and obese males while T2dm and HTN were the highest risk in overweight and obese females.

In Australia, the highest burden associated with overweight and obesity was all linked cardiovascular diseases (37.9%) followed by cancers (19.3%), T2dm (17.2%) and musculoskeletal conditions (16.7%) [78]. Despite the lowered risk, clinicians continue to consider ageing athletes at risk for a cardiac event and musculoskeletal injury [79]. Walsh and colleagues have however, shown a significantly less incidence of injury in MAs than other sporting cohorts [80].

The health benefit seen in MAs is illustrated by the work of Climstein and colleagues [81] who compared the incidence of chronic diseases and conditions in MAs to the Australian general population and reported a significantly lower incidence of anxiety (p < 0.01), depression (p < 0.01) and a trend of a lower incidence of arthritis (−30.4%, p = 0.06). DeBeliso et al. [8] investigated the incidence of chronic diseases and disorders of north American WMG MAs, they found a significantly lower (p < 0.01) incidence of arthritis (rheumatoid and osteoarthritis), HTN, hyperlipidemia, asthma and depression as compared to the US general population.

Body mass index, although widely used and a simple risk factor to attain however, it is not withstanding its limitations which are well recognized [82-84]. Principally, the equation does not take the various tissues (i.e., lean mass, fat mass, bone) into account and this subsequently results in an overestimation and underestimation of BMI. It has been proposed that the standard BMI equation exaggerates thinness in short individuals and fatness in tall and muscular individuals, the latter being athletes. The higher muscle (i.e., lean mass) content in athletes skews BMI as lean mass is approximately 22% denser than fat tissue. Alternative equations for BMI have been proposed, for example Nuttall [85] recommended that the trunk should be considered as a three-dimensional volume and proposed an alternative equation, namely weight/height1.06.

In summary, this review of BMI in MAs provides an initial insight into one indirect multifaceted health benefit seen in MAs (namely lower BMI). Further research is warranted into the health benefits associated with MAs.
